If it is impossible to use the chloride salt of a drug or impractical to include it in the amount required to prevent silver migration, two alternative methods can prevent the onset of silver migration without introducing mobile cations into the delivery reservoir. One is to immobilize the silver by using anion-selective membranes or coatings, or by using chelating agents. Another is to precipitate the silver using chloride ion-containing resins (e.g., those with quaternary ammonium chloride functionality) in the donor reservoir (8).

Silver Chloride as a Consumable Cathode

The silver chloride cathode reaction is given by Eq. 8 in reverse; that is, silver chloride is reduced to form metallic silver and chloride ion. The silver chloride cathode shares many of the qualities of the silver anode, with some additional desirable traits: No electrolyte is depleted by its reaction; it is hydrophilic and therefore wetted by the reservoir electrolyte; and the insoluble reaction product, metallic silver, is electrically conductive, eliminating problems of polarization or isolation of the redox species. Because of this combination of properties, the operating voltage of silver chloride decreases with use, and the utilization of a silver chloride cathode is nearly 100%.

Operation of the silver chloride cathode can lead to an accumulation of chloride ions in the electrolyte. When the electrode is a counter electrode, chloride buildup is not a concern. However, when used as a donor electrode for delivery of anionic drugs, the accumulation of chloride ion can lead to decreased drug flux because of ionic competition. For short duration applications, this

effect may be negligible. However, if the molar concentration of chloride approaches some appreciable fraction of that of the drug, substantial competition will occur. A simple, yet not always practical, way to remain below this threshold fraction is to increase drug content. The amount of additional drug required can be computed from a mass balance calculation. The chloride accumulation rate is determined by the current, according to Faraday's law, and this can be compared with the drug content, which decreases over time as drug is delivered into the body.

FORMULATION COMPOSITION

The formulations of an IDDS are the ingredients in the drug and counter reservoirs, which typically consist of a solvent, a drug salt or a biocompatible salt, and a matrix-forming material. A formulation may also include additives such as buffers, antimicrobial agents, antioxidants and additional electrolyte salts or permeation enhancers. All of these can interact in a complex fashion to affect rate of delivery, biocompatibility, and product shelf life.

Solvent

Drug solubility and stability, in addition to solvent biocompatibility, are obvious considerations when selecting a solvent for a pharmaceutical formulation. For an IDDS, the effect of a solvent on the drug charge state is also an important consideration. Although a neutral drug molecule can be transported into the skin by electroosmosis (9), maximal drug-delivery efficiency is usually achieved if the drug has a net electric charge. For this reason, polar solvents with large dielectric constants are preferred. For example, the dielectric constants of water, glycerol, and ethanol are 80, 42, and 24, respectively. Use of solvents with large dielectric constants results in greater dissociation of the drug salt (i.e., less ion-pairing), enhancing drug mobility during application of an electric field.

Because of its large dielectric constant and inherent biocompatibility, water is the most commonly used solvent. Other cosolvents such as ethanol, glycerol, polyethylene glycol, or polypropylene glycol may be added to enhance drug solubility and drug stability, or to reduce the rate of water evaporation. Sanderson and colleagues (10) used a 40:60 mixture of water and ethanol to enhance the solubility of dobutamine hydrochloride and demonstrated a twofold enhancement in dobutamine flux. However, addition of a cosolvent to enhance drug

solubility may, in some cases, decrease the rate of delivery by electromigration if excessive ion-pairing results.

Jadoul and coworkers (11) studied the effect of adding ethanol and propylene glycol (PG) to aqueous solutions of fentanyl and metoprolol. They reported that drug flux was diminished by up to 80% for solutions containing 60 vol% ethanol or PG. A fourfold drop in formulation conductance was also measured, indicating that more ion association was occurring in the cosolvents. In addition, the solvent may have a direct effect on the skin, thus altering its permeability to drug ions (12). In summary, the effect of a solvent or cosolvent on the drug solubility, ion interactions, and skin permeability are important considerations when choosing the formulations for IDDS.

Drug Salt

In addition to the usual solubility, stability, and biocompatibility considerations, several unique aspects should be considered when selecting the drug salt for an IDDS formulation. First, the counterion must be compatible with the electrochemical reactions occurring at the electrode. As noted previously, halide drug salts are preferred when using a silver anode. For example, fentanyl citrate is used in intravenous formulations, but citrate does not form an insoluble salt with electrochemically generated silver cation. For this reason, a formulation containing fentanyl hydrochloride was specifically developed for use in a patient-activated IDDS for treatment of pain (13). Clinical results using this formulation strategy are summarized latter in this chapter.

As mentioned previously, the extent of drug salt dissociation is an important consideration when selecting a solvent. Therefore, for a particular solvent (e.g., water), selection of a drug salt that more fully dissociates will likely result in more efficient drug delivery. Using aqueous solutions of the acetate, sulfate, and hydrochloride salts of morphine, a correlation between drug salt dissociation and transdermal delivery has been observed (14). From conductance measurements, it was determined that morphine hydrochloride was more fully dissociated in water than were the sulfate and acetate salts. The rate of morphine delivery, at currents ranging from 0.1 to 1 mA, was about 60% greater for the hydrochloride salt than for the sulfate and acetate salts.

Ion mobility (the velocity achieved by an ion per unit electric field) is largely determined by its ionic charge and by the extent of its physical interaction with the formulation or skin. The mobilities of a drug ion and its counterion in a formulation are likely to be different than their mobilities in the skin. In addition, the mobilities of ions that are endogenous to the skin

(e.g., Na^+ , K^+ , Cl^- , HCO_3^-) are likely to be different in the two environments. Therefore, during electromigration the ionic composition of the formulation in the vicinity of the skin can be substantially different than the bulk composition. As a result, it has been suggested that the drug counterion can alter the pH of the interface between the formulation and the skin, and thus alter transport efficiency (10). A twofold enhancement in transport efficiency for the succinate salts of verapamil, gallopamil, and nalbuphine relative to the hydrochloride salts was reported. This result was attributed to the ability of the weakly acidic succinate anion to buffer the boundary layer near the skin surface at about pH 4.8, thus avoiding significant hydronium ion competition.

Matrix

Use of drug dissolved in a liquid solvent is generally adequate for in vitro experimentation, but is not optimal for use in a commercial product. Not only must the formulation be biocompatible, but it must also be readily incorporated into the IDDS during commercial-scale manufacturing, be easily applied by the user, and leave little or no residue on the skin. To achieve these goals, two fundamentally different matrix-based formulation strategies have been adopted for use in IDDS.

In one approach, the drug solution is placed on an absorbent porous material. Such materials include hydrophilic fabrics composed of polyester or nylon, and hydrophilic porous films composed of polyurethane, polyvinyl alcohol (PVOH), or cellulose. To improve hydration kinetics and solvent retention, hydrophilic polymers and/or surfactants have been incorporated into the fabric or foam matrices (15). Examples of hydrophilic polymers are polyethylene oxide, PVOH, poly-*N*-vinyl pyrrolidone, polyacrylamide, polyhydroxyethyl methacrylate, and polysaccharides such as hydroxyethyl cellulose, modified starches, or natural gums. Nonionic surfactants such as Tween 20[®], Neodol 91-6[®], or Tergitol 15-S-7[®] can also be added to enhance the rate of hydration. The water-retentive properties of the polymers, combined with the structural integrity of a fabric or porous film, provide a composite matrix material that will readily absorb the drug solution during the manufacturing process or just prior to use by the patient. The addition of solvent just prior to use can enhance drug stability, particularly for polypeptides and proteins.

The second strategy utilizes drug-containing hydrogels and provides an alternative to the absorption of drug solution by porous composite matrices. With the hydrogel approach, drug salt is mixed with a solvent and a

network-forming polymer to create a viscous solution. The solution is then dispensed into a cavity containing an electrode of the appropriate polarity, and the polymer is crosslinked. To minimize degradation of the drug during the crosslinking process, physical crosslinking is preferred over chemical or radiation-induced crosslinking reactions. For example, polyvinyl alcohol can be dissolved in water, mixed with drug salt, and then frozen at about -20°C . When thawed, a soft, cohesive, water-rich hydrogel results (16). Other hydrophilic polymers such as polyvinyl pyrrolidone or polysaccharides (e.g., hydroxypropylmethyl cellulose) can be added to modify the rheological, adhesive, or water-retentive properties of polyvinyl alcohol hydrogels (17).

In general, polar nonionic polymers have been used as the matrix material in formulations for IDDS. Nonionic polymers are preferred because they typically do not have mobile ionic species and do not interact strongly with drug ions. However, results from studies of drug delivery from matrices composed of ionic polymers have been reported. For example, Gupta and coworkers reported a substantial reduction in cromolyn flux when a hydrogel composed of polyglyceryl methacrylate and water was employed, suggesting a strong interaction between the cromolyn anion and polymer (12).

In contrast, the transdermal iontophoretic delivery of the drug cation, hydromorphone, was enhanced by using a hydrogel formulation composed of water and polyacrylamido-methylpropane-sulfonate (poly-AMPS) (8). A hydrogel composed of water and the acid form of poly-AMPS was imbibed with a stoichiometric amount of hydromorphone base to form the hydromorphone salt of poly-AMPS. Hydromorphone hydrochloride was also added, and the hydrogel was placed in contact with a silver anode. Hydromorphone was delivered at a current density of 0.05 mA cm^{-2} through dermatomed pig skin into a 0.1 M sodium chloride solution. The flux of hydromorphone from the poly-AMPS hydrogel was found to be about twice that of a nonionic PVOH hydrogel. This result suggests that migration of mobile chloride ions from the skin into the hydrogel was hindered by the presence of immobilized sulfonate anions (i.e., ionic repulsion or Donnan exclusion).

Excipients

Excipients such as buffers, antimicrobials, antioxidants and chelating agents may be required for optimal drug stability in IDDS formulations. Several unique criteria when selecting excipients must be considered.

As described earlier, excipients can contact the electrodes of the system. Therefore, excipients must be

screened for their compatibility with the electrodes. Sacrificial electrodes (e.g., Ag and AgCl) are particularly reactive. If inherently nonreactive electrodes are used (e.g., platinum or carbon), then the excipient can be exposed to a relatively large electric potential at the electrode/reservoir interface during system use. In such cases, excipients that are inherently stable should be selected. Excipients are typically evaluated for their electrochemical stability using standard potentiometric techniques (e.g., cyclic voltammetry) before being selected for use in an IDDS formulation.

The effect of an excipient on drug transport must also be considered, especially if it is ionic. If the excipient has the same charge as the drug ion, then it will be delivered into the skin with the drug. In addition to the direct competitive effect on drug transport, the excipient may alter the permselectivity of the skin, causing a change in the drug transport efficiency. If an excipient of opposite charge to the drug ion is chosen, then the effect of the excipient counterion on drug transport must be determined.

Because IDDS formulations usually contain water, the use of lipophilic excipients may not be possible. Instead, salt forms of excipients are often employed. However, excipient salts often contain inorganic cations that are usually much more mobile than most drug cations. The detrimental effects of inorganic cations on the flux of drug cations have been well documented (18). In particular, since inorganic cations are depleted from the formulation more rapidly than the drug cations, the flux of the drug will not be constant but rather will increase with time during system use. The competitive effect of buffer anions on transport of anionic drugs has also been reported (19).

Standard phosphate and citrate buffers have been successfully used in formulations for transdermal iontophoresis of drug ions. However, because small inorganic and organic ions frequently have a negative effect on drug flux due to competition, selecting a buffer can be challenging. Several unique buffering strategies have been developed specifically for use in IDDS. In one strategy, zwitterionic buffering agents are used at their isoelectric pH (20). The net zero charge of the zwitterion largely avoids the ion competition effect. Two preferred zwitterionic buffers are *N*-2-hydroxyethylpiperazine-*N*-2-ethane sulfonic acid (HEPES) and 2-*N*-morpholino-propane sulfonic acid (MES).

Alternatively, the delivery of the buffer ion can be largely eliminated by using cationic buffers in the cathode reservoir and anionic buffers in the anode reservoir, so that the buffer ion moves away from the skin when an electric field is applied. In addition to common weak acids such as citric and phosphoric, the use of amino acids in the anode

formulation has been suggested. Amino acids such as cysteine and histidine would be incorporated at neutral or basic pH, where they are predominately anionic (20).

In another buffering strategy, polymeric materials with pendant acid or base groups (e.g., carboxylic, phosphoric, amines) are dispersed in the formulation (10, 20). Examples of such polymeric buffers are polyacrylic acid and methacrylate/divinyl benzene copolymers (e.g., Amberlite IRP-64[®]). The exceedingly high molecular weight of these polymers renders them essentially immobile in an electrical field. The counterion to the ionic resin must still be considered; preferably it should have the opposite charge of the drug to avoid ionic competition. Alternatively, the counterion to the drug ion can be specifically selected for its inherent buffering capability (10).

In all of these strategies, the goal is to minimize the mobility of the buffering agent, or its counterion, relative to that of the drug ion. This is accomplished by choosing buffers with no net ionic charge, choosing buffers whose mobile species have a charge opposite that of the drug ion, or by increasing the molecular weight of the buffering agent.

Excipients may also be included in the formulation to enhance drug delivery efficiency. For example, Sanderson and colleagues (10) reported a threefold enhancement in delivery of dobutamine after the skin site was pretreated with an anionic surfactant, sodium lauryl sulfate (SLS). They attributed the enhancement in flux to an increase in the negative charge on the skin because of neutralization of fixed positive charges in the skin and to hydrophobic binding of the surfactant to the skin. More specifically, Sanderson and coworkers proposed that an increase in negative charge within the transport pathway enhanced the migration of drug cations by hindering the migration of chloride ions from the body. They noted that while SLS is not biocompatible, the charge-alteration strategy may be useful if other more biocompatible surfactants were identified.

Alternatively, Huntington and Cormier (21) used nonionic surfactants, including dodecanol and 1,2-dodecanediol, to enhance the delivery of the anionic drug, ketoprofen. Because nonionic surfactants are not directly affected by the applied electric field, their use may be preferred over ionic surfactants.

Some drugs and excipients may cause excessive skin irritation (22). Researchers have reduced skin irritation in humans by including an antiinflammatory agent in the formulation (23). Using the moderately irritating antiemetic drug, metoclopramide, they demonstrated improved biocompatibility by adding hydrocortisone to the formulation. As little as 0.05% hydrocortisone in the

formulation significantly reduced erythema at the skin site following treatment. They also reported that hydrocortisone had no effect on the transport of the metoclopramide cation.

Formulation pH

Many drugs have a broad pH range in which drug solubility and stability are adequate for transdermal delivery by iontophoresis. However, optimal drug delivery and biocompatibility are usually restricted to a more narrow range of formulation pH. As discussed previously, skin is a permselective membrane with an isoelectric point of about pH 4. For this reason, formulation pH can affect the selectivity of the skin to cations and anions. As formulation pH increases, skin becomes more negatively charged, thus favoring cation transport. Therefore, to maximize the transdermal flux of a cationic drug, the formulation pH should be as basic as is practical, limited by drug solubility, charge state, stability, and biocompatibility. By analogy, for anionic drugs, acidic formulations are generally preferred.

The effect of formulation pH on skin permselectivity has been clearly demonstrated (24): As the pH of a solution containing salicylate anion was increased from pH 4 to 6, and then to 8, the transdermal flux of salicylate anion at 200 $\mu\text{A}/\text{cm}^2$ decreased from 480 to 192, and then to 174 $\mu\text{g h}^{-1} \text{cm}^{-2}$, respectively. In contrast, with an identical increase in pH, the flux of triethylamine cation increased from 117 to 170, and then to 303 $\mu\text{g h}^{-1} \text{cm}^{-2}$, respectively.

A formulation must provide adequate drug transport, while ensuring good biocompatibility. Several investigators have found that formulation pH can have a substantial effect on skin irritation (10, 20, 25). By measuring the redness at treated sites on hairless guinea pigs, Cormier and Johnson (23) found that skin irritation was reduced by choosing different pH ranges for the anode and cathode formulations. For anode formulations, pH values between 4 and 10 produced the lowest skin responses. For cathode formulations, pH values between 2 and 4 were least irritating.

Electrolytes for Counter Reservoir

An appropriate electrolyte for the formulation in contact with the counter electrode must provide sufficient conductivity to minimize the voltage required during system use. The minimum conductivity, σ , needed to limit the voltage drop, ΔV , across a hydrogel formulation with a thickness of L and a cross-sectional area of A at a current of I is given by the expression:

$$\sigma = (IL)/(\delta VA) \quad (9)$$

For example, a voltage drop of less than 1 V will occur across a hydrogel formulation with a thickness of 0.5 cm and a cross-sectional area of 5 cm² at a current of 0.5 mA, if the formulation has a conductivity of at least 50 μ S/cm.

Because formulation conductivity is sensitive to solubility and ion-pairing effects, it can be used to characterize alternative formulations during formulation development. Gangarosa and colleagues (26) and Yoshida and Roberts (19) provide examples of the effect of drug and electrolyte conductivity on formulation performance in IDDS.

In addition to rendering the formulation sufficiently conductive, the ion delivered from the nondrug formulation must be biocompatible. Irritation resulting from use of four inorganic electrolytes has been reported by Anigbogu and coworkers (27). They reported that use of 0.9% NaCl or KCl in the anode reservoir at current densities of 0.5 mA/cm² and 1 mA/cm² for 1 h elicited no skin irritation in rabbits. In contrast, the use of 0.9% CaCl₂ or MgCl₂ caused moderate erythema.

Using weak acids and bases as electrolytes for the counter reservoir formulation at the proper pH (i.e., pH < 4 for cathode formulations and pH > 4 for anode formulations) provides adequate biocompatibility and low skin resistance (20). Low skin resistance is advantageous since less voltage output is required from the control circuit, and therefore a smaller battery may be required, potentially reducing the size and cost of the IDDS.

For current densities at or above 0.2 mA/cm², the sensation associated with transdermal iontophoresis is determined by the type of ion being delivered into the skin. When human subjects compared the sensation experienced during iontophoresis of different salt solutions applied to the right and left forearms, delivery of calcium caused less sensation than delivery of phosphate, magnesium, and zinc, which caused less sensation than delivery of chloride, acetate, citrate, and sulfate, which in turn caused less sensation than delivery of lithium, potassium, and sodium. In general, multivalent ions were found to cause less sensation than monovalent ions (28).

ELECTRONIC COMPONENTS

The unique electrical nature of an IDDS provides an enhanced level of control over drug delivery. In addition, the ability to provide information feedback is not often available in other modes of drug delivery.

There are two general electrical approaches used in iontophoretic treatments: One is to control the applied voltage; the other is to control the applied current. A simple example of a controlled-voltage circuit is a battery that applies a constant voltage to the electrodes. However, as will be pointed out later, the skin resistance is neither constant between individuals nor is it static from the start to finish of a single application. Thus, a constant voltage approach will result in variable current. Since the rate of drug delivered is directly proportional to the current passed, a controlled-current approach is generally preferred.

The electrical control components of an IDDS may be divided into two elements: the power source and the control circuitry.

Power Source

The electrical power source for portable IDDS is a battery. Commercially available primary batteries have cell voltages that range from about 1.2 to 3.0 V. To overcome the resistance of the skin and achieve the desired current, it may be necessary to use higher voltages. Voltage can be increased by combining cells in series, or by using circuitry to "step-up" the voltage at the cost of drawing a larger current from the battery. This additional current drain adds to the total battery capacity needed to provide the required therapy. Thus, the total battery capacity required is the sum of that needed to support the therapy plus any "overhead" associated with the electrical circuitry.

The first objective of the circuitry is to control the amount of drug delivered. For a zero-order (constant-delivery) system, for example, a specified current should be maintained regardless of the resistance of the application site. Computing the power requirement in this case is difficult because the resistive load of the skin

Fig. 2 Skin resistance of various body sites as a function of time of current application. (From Ref. 29.)

depends on both the application site and the time elapsed since current has been initiated (29). Fig. 2 shows the skin resistance at different application sites in response to the application of 1 mA to a 4 cm² area. Two minutes before applying 1 mA, a small current of 10 μ A was applied to determine the skin resistance, which was highly variable and had a mean value of about 200 k Ω . Just 1 s after applying a current of 1 mA, the resistance decreased substantially to 16 ± 4 k Ω . As time progressed, the resistance continued to fall and all sites appeared to approach a quasi-steady-state value of 7.4 ± 1.3 k Ω . The small relative standard deviation (RSD) of the quasi-steady-state resistance of 18% compared with an initial RSD of 92% indicates that all body sites tested tend toward a common resistance, despite the large differences that are present prior to application of current. This fact has been attributed to an increase in ionic conductivity of the skin due to an increase in ion concentration within the stratum corneum and to “activation” of shunt pathways (3).

For a typical initial skin resistance of 200 k Ω , 200 V would be required to achieve a current of 1 mA. Therefore, a typical system having a modest output voltage of 10–20 V will operate below the desired current (i.e., will be noncompliant) during the initial moments of current application. However, because the resistance drops quickly, a voltage capability of about 10–20 V is generally sufficient to achieve compliance within an acceptably short time of about 1 min or less.

Control Circuitry

A controlled current circuit does not necessarily require a high level of electronic sophistication. A simple field-effect transistor with a feedback resistor can maintain the current delivered from a battery at a constant value over a wide range of skin resistances. Other types of delivery requirements such as pulsed current, patient-controlled on-demand dosing, dose titration, ramp-up or ramp-down dosing, and other special waveforms can be addressed with control circuitry. In these cases integrated circuits are usually employed to minimize system size.

Visual and audio feedback information is provided to the user by light-emitting diodes (LED), liquid crystal displays (LCD), and piezoelectric transducers. This information can indicate that the system is working, show errors or warnings, signal system maintenance needs (such as battery replacement), or display the amount of drug that has been delivered.

The ability of an IDDS to electronically control drug delivery gives rise to another potential advantage; the opportunity to create sensor-based or “closed-loop” therapy. If an appropriate sensor is available to measure

Fig. 3 Exploded view of an iontophoretic drug delivery system showing major components: top housing, printed circuit board assembly, a bottom housing containing reservoirs for placement of electrodes and hydrogels, and an adhesive laminate. (Diagram from International Patent Publication Number WO 96/39222.)

a biological response (e.g., to measure blood glucose levels in response to the delivery of insulin), then circuitry can be used to modulate the output current, and therefore drug delivery. In so doing, an automated, closed-loop system is created that ensures the proper amount of drug is delivered and avoids both over- and under-dosing the patient. As shown in Fig. 3, the electronic components are typically mounted on a printed circuit board and mounted within a protective housing containing the electrodes and formulation hydrogels.

CLINICAL ASSESSMENT OF SYSTEMIC DELIVERY

In the following clinical case studies, a number of delivery attributes discussed in earlier sections are exemplified. In

addition, *in vitro* methodologies are briefly discussed to highlight the good correlation possible with observed *in vivo* results.

Fentanyl Clinical Study

Fentanyl has a molecular weight of 336 Da in the base form, an aqueous solubility of about 24 mg/ml as the HCl salt, and a charge of +1 over a wide pH range. Fentanyl is a synthetic opioid widely used in anesthesia and analgesia. A passive transdermal system is available for the treatment of chronic pain (Duragesic®, Janssen Pharmaceutica). This patch delivers fentanyl through the skin continuously over 72 h. For the management of acute pain, such as post-operative pain, the slow onset of action of fentanyl obtained with passive transdermal delivery is not appropriate. However, fentanyl delivery from an IDDS to quickly attain therapeutic blood levels and a quick onset of analgesia has been demonstrated clinically (30, 31). In addition, the electrical nature of iontophoresis allows the patient to initiate a dose of fentanyl when in pain, which is not possible with passive delivery (32).

The IDDS used in the clinical study consisted of a reusable, battery-operated controller capable of delivering user-actuated doses when connected to a disposable patch-like drug unit. The drug unit had a silver anode and silver chloride cathode in intimate contact with hydrogel reservoirs within a flexible foam housing. The drug unit contained 5 mg (base equivalent) of the hydrochloride salt of fentanyl and the donor hydrogel reservoir had a skin

contact area of 2 cm². The disposable drug units were applied to the upper outer arms of healthy volunteers. The opioid effects of fentanyl were blocked in the volunteers by oral administration of naltrexone every 12 h.

The study was a four-treatment crossover (three with IDDS plus an IV treatment), conducted in 12 subjects. All treatments delivered fentanyl for the first 20 min of every hour for 24 h. The three IDDS treatments employed currents of 150, 200, and 250 μ A, while the IV treatment infused 50 μ g of fentanyl. Blood samples were collected, and serum fentanyl concentrations were measured using a specific radioimmunoassay. Plasma data collected during and immediately following the 1st, 13th, and 25th treatments are shown in Fig. 4. The gradual upward shifts in concentration over time indicate a baseline increase due to incomplete fentanyl clearance between the hourly doses. For all treatment types, serum fentanyl concentrations rapidly increased within a few minutes after the start of each dose.

The average drug input fluxes during the 20-min dosing periods between hours 24 and 25 were calculated to be 81, 108, and 138 μ g/h/cm² for currents of 150, 200, and 250 μ A, respectively. These values, the mean maximum plasma concentration values, and the total AUC values (over the same time period) for the three IDDS treatments all increased proportionally with current. These results agree with theoretical expectations expressed by Equation (1). In addition, the variabilities in the fentanyl pharmacokinetic parameters were similar for the IDDS and IV treatments, indicating that the IDDS doses were delivered with an accuracy similar to the IV infusions.

The *in vivo* flux values for fentanyl agree closely with *in vitro* flux values obtained with human cadaver skin. *In vitro* transdermal experiments with fentanyl were conducted using two-compartment permeation cells.

Fig. 4 Mean serum fentanyl concentrations for 12 healthy volunteers receiving fentanyl intermittently (20 min each hour over a 24-h administration period) from an iontophoretic system at three currents, and from IV fentanyl infusion (50 μ g for 20 min hourly). Serum fentanyl concentrations were measured during and immediately after the 1st, 13th, and 25th doses. (From Ref. 31.)

Fig. 5 Comparison of *in vitro* ($n = 5$) and *in vivo* ($n = 13$) fentanyl flux as a function of applied current. (From Ref. 13.)

Heat-stripped human epidermis was oriented so that the stratum corneum surface contacted the fentanyl hydrochloride solution in the donor compartment. The donor solution pH and fentanyl concentration were very similar to the pH and concentration of the donor formulation used in the clinical study.

To establish a good in vitro/in vivo correlation, the composition and ionic strength of the receptor solution must be adjusted (18). For fentanyl, the best correlation was obtained with a receptor solution comprised of a 10-fold dilution of modified Dulbecco' phosphate-buffered saline (without calcium or magnesium) at pH 7.4. The currents tested in vitro ranged from 0 to 400 μ A and were applied to a silver anode and a silver chloride cathode using a constant current power supply. The in vitro data presented in Fig. 5 clearly demonstrate the expected linear dependence of fentanyl delivery on current and the excellent correlation to the in vivo data.

Luteinizing Hormone-Releasing Hormone Clinical Study

Systemic delivery of polypeptides, proteins and oligonucleotides pose many significant delivery challenges to pharmaceutical scientists. Because of their extensive metabolism in the gastrointestinal tract, they are generally not good candidates for oral administration. These compounds typically have large molecular weights, are hydrophilic, and have a pH-dependent electrical charge. These qualities also make them poor candidates for passive transdermal delivery but excellent candidates for iontophoretic delivery (33).

Luteinizing hormone-releasing hormone (LHRH) is a native reproductive hormone containing 10 amino acids with a molecular weight of approximately 1200 Da and a charge of +1 near neutral pH. Pulsatile delivery of LHRH by the hypothalamus stimulates the production of gonadotropins, such as luteinizing hormone (LH), by the pituitary gland for the maintenance of normal female reproductive function. In contrast, continuous secretion of LHRH shuts down the reproductive axis.

It is possible to achieve continuous or pulsed LHRH delivery profiles using transdermal iontophoresis. Heit and colleagues have demonstrated that continuous transdermal iontophoresis of LHRH is possible (34). Continuous transdermal iontophoresis of leuprolide, a nine-amino acid analog of LHRH, has also proved clinically successful (35).

The iontophoretic delivery of discrete pulses of LHRH using an IDDS was investigated in a clinical study with healthy male volunteers (36). The clinical system comprised an 8 cm² hydrogel formulation containing 15 mM LHRH as the hydrochloride salt in contact with a

Fig. 6 Mean plasma LHRH concentrations of eight healthy male volunteers receiving four 15-min doses of LHRH at 0.1 mA/cm² every two h, and an IV LHRH bolus dose of 5 μ g. Mean plasma LH levels resulting from the iontophoretic LHRH doses are also plotted. (From Ref. 36.)

silver anode. Plasma LHRH and LH concentrations obtained in eight subjects receiving one 15-min pulse at a current of 0.8 mA (0.1 mA/cm² current density) every 2 h for 8 h are shown in Fig. 6. The plasma LHRH concentration obtained following the administration of a single 5 μ g IV bolus is also shown as a reference. These results demonstrate that pulsatile delivery of LHRH is possible using reasonable iontophoretic conditions. Significantly, the plasma LHRH profiles obtained with an IDDS are comparable with those obtained following IV bolus administration. The four consecutive 15-min doses resulted in plasma LHRH profiles with sharp peaks (C_{\max} up to 450 pg/ml). Plasma LHRH levels rapidly declined to negligible baseline values between doses, consistent with IV administration. The plasma LHRH levels rose and fell much more rapidly than profiles obtained with subcutaneous injections (37).

Following each dose of LHRH, the pharmacodynamic plasma LH response also followed a pulsatile pattern with a mean maximum concentration of about 26 mIU/ml. As was discussed earlier for fentanyl, the variability in the iontophoretic LHRH plasma data was comparable to that obtained with IV administration.

While iontophoresis has not been widely employed, the field is rapidly evolving. The development of small patch-like devices for glucose extraction and for systemic delivery of therapeutic agents is occurring at several companies, including Cygnus, Becton Dickinson, and ALZA. If commercially successful, these efforts would

greatly expand the applications of iontophoresis for systemic therapy.

INTRODUCTION

Using the inhalation route to deliver therapeutic aerosols is a common practice in the treatment of patients with various airway diseases. Drug delivery via inhalation offers many advantages in the administration of pharmaceutical compounds, because the drugs are delivered directly to the site of action. Therefore, the required therapeutic dose for each treatment is lower than if the dose is administered via oral or parenteral routes. As a consequence, the inhalation route reduces adverse effects due to systemic absorption and intensifies the amount of drug deposited to the targeted tissue. In the U.S. market, bronchodilator, anticholinergic, anti-inflammatory, and corticosteroid drugs are common inhaled dosage forms used for the treatment of respiratory diseases, such as asthma and COPD. Additional drug classes, such as antibiotics, antifungals, and antiviral compounds, are also used or under development for topical delivery via inhalation. Further, new inhaled applications are being developed for the treatment of systemic diseases. These products include both small and macromolecules. Pulmonary delivery of peptides and proteins is a rapidly growing area of inhaled drug delivery, spearheaded by the development of inhaled insulin for treatment of diabetes.

An aerosol is defined in its simplest form as a collection of solid or liquid particles suspended in a gas such as air. Aerosols are two-phase systems consisting of the particulates and the gas in which they are suspended (1). Aerosol science has been studied for many decades in various disciplines, especially related to environmental sciences, to understand the health effects associated with exposure to air pollutants. These activities have improved our understanding of the dynamic behavior of aerosol particles and their relative effects on human health, but also laid the foundation for the pharmaceutical industry to use inhalation of aerosols for therapeutic purposes. Pharmaceutical aerosols deliver therapeutically active drug compounds to the human respiratory tract for local or systemic actions. This dosage form is intended to be inhaled through either the mouth or the nose. The

increasing use of inhalation therapy has been mainly driven by the confluence of three factors:

1. Advances in aerosol generation technology, which provide more efficient and controlled delivery of aerosolized pharmaceutical compounds into the human respiratory airway;
2. Advances in biotechnology, with the development of new therapeutic agents that are often difficult to deliver by other routes of administration;
3. A better understanding of the pathophysiology of disease, which allows physicians and scientists to envision a broader range of therapeutic options.

Those involved with the pulmonary delivery of therapeutic agents are challenged in all three areas, especially the first two. We can now develop new therapies, but we must be certain that we can reproducibly deliver those therapeutic agents to the desired site, in the dosage and form in which they will be most effective (2).

The benefit of using the respiratory airways as a route for drug delivery has been increasingly explored over the last 10 years (3). The large surface area of the human respiratory system, sometimes compared to the size of a tennis court ($\sim 100 \text{ m}^2$), is an attractive target site for pulmonary delivery of drugs intended for absorption into the blood. Drug administration via inhalation has many advantages for the systemic delivery of pharmaceutical compounds such as proteins and peptides, which are often degraded when delivered through the GI tract and avoid the need for repeated injections (4).

Inhaled aerosols also provide high drug concentrations in the respiratory tract. The treatment of airway diseases by aerosol inhalation is beneficial because of intensified localized drug deposition and fewer side effects. Consequently, smaller doses are needed to achieve the therapeutic level in the lungs via inhalation thereby avoiding high systemic levels of the drug. Therefore, inhaled drug aerosols have become the standard clinical approach for managing asthma, respiratory distress syndrome (RDS), chronic obstructive pulmonary disease (COPD), cystic fibrosis, and other respiratory tract diseases (5). Despite

the spectrum of opportunities that now exists for new inhaled therapies, successful development of pulmonary drug products is a challenging task. The problems and barriers are multidisciplinary in nature, perhaps explaining why this field has not accelerated faster (6).

Using aerosolization to administer drugs to the respiratory airway dates back to the early part of the 20th century, when the pneumatic nebulizer was used as a drug delivery device. Fig. 1a shows some examples of the first types of nebulizers used, the simplest of which were powered by squeezing the bulb attached to the device. Fig. 1b shows more modern units such as pMDIs.

The nebulization principle for the squeeze-bulb nebulizers is the same as many conventional nebulizers. Liquid is forced through a small critical orifice. The particle size of aerosol generated from the early squeeze-bulb nebulizers was generally large (due to the inability to accurately machine small holes) and, therefore, largely unsuitable for human inhalation. However, the concept of delivering drug products via inhalation was an important milestone that established the foundation for developing better pulmonary drug delivery technology.

The modern pressurized metered dose inhaler (pMDI) was developed between 1955 and 1956. However, the pMDI had its roots in research carried out many years before (7). During the 1930s and 1940s, the discovery of liquefied propellants (chlorinated-fluorocarbons or freon propellants) such as CFC12, CFC114, CFC11, and CFC22 was a major step in the realization of a portable inhaler. However, the first pMDI was not invented until 1956, when the metering valve used in the device was developed and patented (7).

The invention of the first pMDI by Riker Laboratories (now 3M Pharmaceuticals) was described in detail recently, and was approved by the FDA in March 1956 (8). The Medihaler-EptTM and Medihaler-IsoTM were launched at the same time. Illustrations from the first brochure of these inhalers are presented in Fig. 2. The Medihaler-Iso was changed to accommodate suspension formulations during 1957. This proved particularly useful for formulating difficult to solubilize drugs, such as many of the steroids later developed for the treatment of asthma. The successful innovation of the pMDI established the foundation for the development of drug delivery via

Fig. 2 The metered dose inhaler. (a) Medihaler-Ept and (b) Medihaler-Iso. (Courtesy of Charles Thiel.)

respiratory airways and remained the primary small volume nebulizer for the next 40 years.

Successful administration of any pharmaceutical compound to the human respiratory airway requires the generation and delivery of the drug in the form of an suitable for human inhalation. The human airway is a very complex structure that has evolved to serve two purposes: 1) exchanging gases vital to metabolism (O_2 and CO_2) and 2) defending against foreign particulates from entering the lungs. The generation of drug aerosols and their site of deposition in human lungs are dependent on many factors, such as the physical and chemical properties of aerosol particles, the mechanism of action and quality of performance of the drug delivery device, the patient's breathing pattern, and the morphometry of the human lungs. These factors are significant because:

- Aerosol properties, such as particle size distribution, aerosol velocity, and hygroscopicity, affect aerosol deposition in the human lungs. Aerosol size distribution, including mass median aerodynamic diameter (MMAD) and geometric standard deviation (GSD), is one of the most important variables in governing the site of droplet or particle deposition in the lungs (3).
- Device characteristics play an important role in the delivery of pharmaceutical compounds to human lungs. The mechanism by which aerosols are created affect particle size distribution, kinetics of aerosol delivery, and the reproducibility of drug dosing from the delivery device. These factors are key to controlling the delivery of a constant amount of drug aerosol across a diverse patient population.
- The breathing patterns or maneuvers of a patient can also significantly affect the site of aerosol deposition in the human lungs, even of aerosols with similar characteristics (e.g., MMAD and GSD). Aerosol deposition mechanisms in the airway mainly consist of sedimentation, inertial impaction, and diffusion. Pharmaceutical aerosols deposit mainly by sedimentation and impaction. Therefore, aerosols delivered under high velocity conditions, either due to high ballistic velocity produced by the device or due to high patient inspiratory flow rates, result predominantly in deposition due to inertial impaction, markedly enhancing conducting airway deposition. Conversely, deposition in the peripheral lung can be promoted by decreasing the velocity of an aerosol during inhalation. Further, deposition of these particles that reach the deep lung can be enhanced by a postinspiratory pause (i.e., breath-hold), allowing particles to settle more completely.

- Morphometry of the upper and lower airways will also affect the drug deposition in the lungs. Anatomical conditions such as airway size, disease status, and degree of obstruction are different from patient to patient; thus there will be variability in the site of drug deposition between patients.

The inhalation drug delivery devices currently available commercially consist of metered dose inhalers (MDIs), dry powder inhalers (DPIs), and nebulizers. The advantages and disadvantages of those devices have been reviewed extensively in the literature. This article will focus on the inhalation of aerosols generated from liquid systems using either small volume inhalers, or larger home or clinical nebulizers. Aerosols produced in powder form are covered in another chapter. Various drug delivery devices, including those available commercially and those under development, will be discussed in detail, so that the reader will have a better understanding of the advantages and disadvantages of those devices for pulmonary drug delivery. An emphasis will be given to new pulmonary drug delivery device technology in development, and its potential application to deliver pharmaceutical compounds for both local targeting and systemic absorption of drugs intended to act outside the lung. Over the last 10 years, many innovations have occurred in the area of inhalation drug delivery stimulated by advances in aerosol generation technology and the demand created by new biopharmaceuticals.

COMMERCIALLY AVAILABLE PULMONARY DELIVERY TECHNOLOGY

The inhalation drug delivery devices currently available commercially consist of metered dose inhalers (MDIs), dry powder inhalers (DPIs) and nebulizers. The effective performance (or lack thereof) of the inhalation devices is well recognized as being crucial in how effective a pulmonary delivered drug is in the treatment of diseases, both topical and systemic disorders. In order for a drug to be effective by inhalation, the generated aerosol must be of proper size to be deposited in the targeted location. The patient needs to inhale the drug formulation properly, and the drug must be deposited with sufficient quantity at the action site so that it can be absorbed or distributed effectively. The drug delivery devices available commercially have been used widely for the treatment of airway diseases such as asthma and chronic obstructive pulmonary diseases (COPDs). Such treatment is effective mainly because of the wide therapeutic index of the drug compounds. It is useful to review the advantages and

disadvantages of current device technologies to provide a better understanding of how the devices are used by patients and what kind of improvements are needed to deliver various drug compounds by inhalation. This article is limited to discussion of devices that generate liquid drug aerosols as solutions, suspensions, and emulsions^a

There are several ways to categorize drug delivery devices. The inhalation drug delivery devices discussed in this chapter are categorized according to their operating principles or fundamental mechanism of generating aerosols.

Pressure-Driven Devices

Jet nebulizers

The jet nebulizer has been used for many years to treat airway diseases both in the clinical setting and in home use. The jet nebulizer utilizes compressed gas from an air source either from a hospital air line or from a portable compressor to convert the liquid drug solution into small droplets by forcing the liquid through a small hole known as a critical orifice. Atomization occurs as a result of the disruption of the surface tension holding the liquid together by the action of internal and external forces. In the absence of such disruptive forces, surface tension tends to pull the liquid into the form of a sphere, since this has the minimum amount of surface energy (9). The droplets produced by atomization contain many large drops, which will undergo further disruption to form small particles. The particle size of the droplets will depend not only on the kinetic energy used during the nebulization, but also the pore diameter of the critical orifice and on the physical properties of the liquid formulation.

The jet nebulizer is driven by air pressurized typically at 20–40 psi. The compressed air accelerates through a narrow orifice to break the bulk liquid into sheets, jets, films, or streams. Those ligaments are accelerated to a velocity sufficient to impact on baffles or on the nebulizer wall. The outgoing air becomes saturated with water vapors derived from the liquid retained in the nebulizer, and this has two important consequences:

1. The nebulizer is cooled and reaches an equilibrium temperature approximately 10°C below ambient, so that the patient inhales a relatively cool aerosol cloud.
2. The evaporation of water causes the concentration of solutes to increase with time as the vehicle carrier evaporates (10).

^aDevices producing liquid dry powder aerosols is discussed in *Inhalation, Dry Powder*, page 1529–1544.

Droplet formation: A general theory for the formation of droplets by nebulization has not been fully developed, although the understanding of the nebulization principle has been improved with mathematical modeling. A rigorous mathematical description of droplet formation requires knowledge of distribution of aerodynamic pressure on the droplet surface and the interaction of this pressure with internal forces acting on the droplets. Therefore, before further discussing of the effect of various parameters on the nebulization performance, it is beneficial to consider briefly the various ways in which a single droplet of liquid can break up under the action of aerodynamic forces. Once the droplets are generated using a compressed air source during the primary atomization, unstable droplets experience further disintegration to form smaller particles, which is referred to as “secondary atomization.” The formation of a single droplet under the aerodynamic forces exerted by the external sources, together with the internal forces of the liquid formulation, such as surface tension and viscosity, dictate the formation of the droplet. The relationship between these forces was described by Klusener (11), who offered the following equation:

$$P_1 = P_a + P_\sigma = \text{constant} \quad (1)$$

where P_1 is the internal pressure at any point on the droplet surface, P_a is the external aerodynamic pressure due to the compressed air source, and P_σ is the pressure caused by the surface tension. From the equation, it is observed that a droplet can maintain its stability as long as the change in the air pressure, P_a , is balanced by a corresponding change in the pressure caused by surface tension, so that the internal pressure remain constant. When the aerodynamic pressure is greater than the pressure due to surface tension, the external pressure will deform the droplet in order to reduce the pressure by surface tension to maintain the constant internal pressure. This deformation will continue to break up the droplet into smaller particles (9).

For a formulation with low viscosity, such as aqueous formulation, the viscous force is relatively small compared with the surface tension force. Under such relative conditions, a dimensionless parameter can be obtained, as shown in Eq. 2 (8). For a given liquid with low viscosity, the critical condition for the droplet to break up occurs when the aerodynamic force equals the surface tension, expressed as

$$C_D \frac{\pi d^2}{4} 0.5 \rho V^2 = \pi d \sigma \quad (2)$$

where C_D is the coefficient of drag, d is the diameter of the droplet, ρ and σ are the density and surface tension of

the liquid, respectively. From the above equation one can calculate the maximum stable droplet diameter,

$$d_{\max} = \left(\frac{8\sigma}{C_D \rho V^2} \right) \quad (3)$$

and the critical velocity at which the droplet will disrupt

$$V_{\text{crit}} = \left(\frac{8\sigma}{C_D \rho d} \right)^{0.5} \quad (4)$$

The equation can also be expressed as the dimensionless parameter called the Weber number, as

$$We_{\text{crit}} = \left(\frac{\rho V^2 d}{\sigma} \right)_{\text{crit}} = \frac{8}{C_D} \quad (5)$$

which is the ratio of external aerodynamic force to surface tension force. Using the above equations, the maximum diameter at a particular critical velocity can be estimated. However, it should be noted that the estimated diameter results from only the process of primary atomization. Secondly, atomization will generally decrease and exaggerate the particle size distribution. Additionally, when a droplet impacts a baffle immediately after the primary atomization, the droplet diameter drops sharply. Baffles are used in nebulizer systems to help control the particle size distribution of the droplets so that generated aerosols are within a desired particle size range, usually with mean values that are less than 10 μm and preferably less than 5 μm , for effective deposition in the human lungs.

Effect of physical properties of formulation: The physical properties of the formulation, such as viscosity and surface tension, are important parameters that affect the process of nebulization. Surface tension can be considered as a consolidating influence that attempts to minimize the production of increased surface area, and the liquid viscosity exerts a stabilizing influence by opposing any change in the shape of droplets as they are produced (12). Studies (13) have shown that the droplet size is proportional to the liquid surface tension for low-viscosity liquids, while the density has only a small effect on the droplet size. The effect of viscosity on the droplet size seems to be complex. Research by Searls and Snyder (14) showed that high-viscosity liquids not only have increased nebulization time (decreasing the mass output), but also reduced mean particle size. However, Hinds et al. (15) reported little change in droplet size with viscosity ranged from 17 to over 100 cP using a Laskin aerosol generator operated at 20 psi.

An extensive study was conducted by McCallion et al. (16) investigating the effects of different physicochemical properties on the performance of the jet nebulizer.

Materials with different viscosity and surface tension were nebulized using three different nebulizers, Pari LC (Pari-Werk GmbH, Starnberg, Germany), Sidestream (Medic Aid, Pagham, United Kingdom), and Cirrus (Intersurgical Complete Respiratory Care, Workingham, United Kingdom). However, only data from the Pari LC nebulizer were presented in the paper. The particle size distribution of the aerosols was quantified using laser diffraction, which has been shown by Clack (17) to be a robust and reliable technique having good correlation with in vivo deposition data. Table 1 shows the experimental data for different formulations obtained using the Pari LC jet nebulizer. The mass median diameters were obtained using two nebulization flow rates, 6 and 8 L/min, respectively. The authors concluded that the more viscous fluids tended to produce smaller droplets. Within a specific range of the surface tension, of approximately 70 dyne/cm (70.0–72.9 dyne/cm), the mass median diameter decreased from 3.2 to 2.5 μm as the viscosity increased from 1.0 to about 6.0 centipoise. The same was true for surface tension of approximately 20 dyne/cm: as the viscosity increased, the particle size decreased. The effect of surface tension on particle size distribution was not as clear. However, the authors pointed out that a correlation between surface tension and mass median diameter appeared to exist when the fluid systems were analyzed separately. In glycerol and propylene glycol solutions, surface tension was directly proportional to droplet size, while the converse was true for silicone fluids. A trend was reported for the other two nebulizers tested, but no data were presented (18, 19).

Drug concentration effects: Because of the large volume of air used during nebulization, there is continuous evaporative loss of any solvent, such as water. This phenomenon has been described in several studies (20–23). Theoretically, the increase in drug concentration will continue until the solute concentration in the reservoir reaches the limit of drug solubility, at which point precipitation may occur. In practice, many drugs used in nebulizers (such as bronchodilators) are very hydrophilic, and the nebulizer solutions are formulated at concentrations well below the solubility limit (3), so there is little issue with precipitation. However, this results in changing particle size distribution with variable deposition patterns, and a change in the unit dose given per unit time. Collectively, this produces variable and unpredictable deposited doses for many drug products. The magnitude of the change in solution concentration is difficult to quantitatively predict and depends strongly on the formulation, nebulization condition, and type of nebulizers. Niven (12) has recently derived a mathematical equation based upon the early work by Mercer (21) to

Table 1 Average mass median diameter for fluids nebulized in a Pari LC nebulizer

Fluid	Viscosity (cP)	Surface tension (dyne/cm)	Mass median diameter (μm)	
			6 L/min	8 L/min
Water	1.00	72.8	3.6	3.1
Ethanol	1.19	24.1	3.0	2.5
Glycerol 10%	1.31	72.9	3.1	2.9
Glycerol 25%	2.09	72.2	2.6	2.4
Glycerol 50%	6.03	70.0	2.5	2.0
P. Glycol 10%	1.50	62.0	1.9	1.6
P. Glycol 30%	3.00	52.0	1.6	1.5
P. Glycol 50%	6.50	45.0	1.3	1.2
S.F. 200/0.65 cs	0.49	15.9	3.3	2.9
S.F. 200/1 cs	0.82	7.4	2.4	2.0
S.F. 200/5 cs	4.60	19.7	1.6	1.3
S.F. 200/10 cs	9.40	20.1	1.7	1.7

S.F. 200/50 cs	48.00	20.8	1.2	1.1
S.F. 200/100 cs	97.00	20.9	1.4	1.4

P. Glycol = Propylene glycol; S.F. = silicon fluid.
(Adapted from Ref. 16.)

describe the relationship of drug concentration in the nebulizer as a function of time. The drug concentration obtained by Mercer (21) was expressed as

$$C(t) = C_0 \left(\frac{V_0}{V_0 - (W + S)Ft} \right)^{(WW+S)}$$

(6)

where *W* and *S* are the solution output and solvent output per liter of air (ml/L air) respectively as shown in Fig. 3. *V*₀ is the initial fill volume into the nebulizer, and *F* is the nebulization flow rate. A more user-friendly version of the equation was derived (12) and expressed in terms of drug mass output that might be of more practical use in predicting drug output from a nebulizer for a range of operation conditions as claimed by the author:

$$M_{out} = M_0 \left[1 - \left(\frac{V}{V_0} \right)^{(WW+S)} \right]$$

(7)

where *M*₀ is the initial amount of drug in the solution, and *V* is the solution volume at any time, *t*, expressed as

$$V = V_0 - [W + S]Ft.$$

(8)

Newman et al. (24) evaluated the concentration change using four different jet nebulizers, with a gentamicin solution, which is used to treat patients for cystic fibrosis. The types of nebulizers used were the Bird micronebulizer, DeVilbiss 646, Bard Inspiron mini-neb, and Medic-Aid Upmist. All were operated at four different air flow

Fig. 3 Schematic diagram of nebulizer output. Droplets small enough will be carried out by air stream (route A), and the large droplets will be either recycled to the nebulizer reservoir (route B) or carried out by the outgoing air stream (route B₁). Some of the solvent will be evaporated (route C). (Adapted from Ref. 12.)

rates: 6, 8, 10, and 12 L/min. Nebulization time was defined as 30 s after the last visible release of aerosol. The concentration of the drug solution left in the nebulizers was then measured using an Osmometer. The initial drug concentration was 40 mg/ml for both fill volumes. Table 2 shows the final concentration of gentamicin solution at different nebulization flow rates.

It was found that the ratio of final to initial drug concentration ranged from 1.35 to 1.70 for the 2 ml fill volume, and from 1.45 to 1.96 for the 4 ml fill volume. The ratio did not vary significantly between the four different nebulization flow rates, but was significantly higher ($p < 0.01$) for the 4 ml fill volume than for the 2 ml fill volume, indicating that the larger volume allowed more time to concentrate the reservoir drug solution. The same phenomenon was observed using a albuterol solution, and the drug concentration increased after the nebulization (25). It was also found that the concentration ratio decreased with the increase in solution fill volume, which is different from the results shown in Table 2. However the discrepancy may result from the different nebulization sources, where dry oxygen versus an electric powered air compressor were used in the experiment (25).

Temperature effects: It is well known that the nebulizer solution cools during nebulization, because a large amount of compressed air is used to generate aerosol particles (20, 21). The temperature of the nebulizer solution decreases several degrees (5–10°C) due to the evaporation of solvent in the solution during the first several minutes of nebulization until a new heat balance is established. Some cooling of the solution in the nebulizer due to adiabatic expansion of the compressed air source may be absorbed by the thermal energy released by break-

up and impact of the liquid (26). The magnitude of temperature change in the nebulization solution depends on many factors, such as heat capacity, properties of nebulizer material, ambient conditions, and the humidity and temperature of the compressed air. Fig. 4 shows the change in solution temperature as a function of nebulization time (20). Four different types of nebulizers were used together with different air compressors to aerosolize a sodium chloride solution. The solutions in the nebulizers were initially at ambient temperatures (approximately of 23°C).

Different nebulizers had different temperature reduction profiles, depending on the compressed air flow rate applied during the nebulization, as pointed out by the authors. The solution temperature falls to a steady value, T_s , which is 5–6°C below the ambient temperature at the nebulization flow rate of 6.3–5.0 L/min, and 11–15°C at 8 L/min air flow rate.

Drug aerosol delivery efficiency and particle size distribution: Delivery efficiency of aerosolized drug product and particle size distribution are the two most important parameters in assessing the performance of a nebulizer for aerosol therapy. The aerosol output from the nebulizer depends mainly on the nebulizer type, drug formulation, solution volume placed in the nebulizer, and the applied air pressure (and hence the airflow through the nebulizer). The simplest method to calculate the output from a nebulizer is to weigh the nebulizer before and after the nebulization, often expressed as the solution volume output per unit time (i.e., mg/min). However, this method of calculation is subject to at least two possible error sources: 1) neglecting the change in solution density when it is used to transfer the mass output per unit time to

Table 2 Final drug concentration (mg/ml) in the nebulizer reservoirs

Nebulizer type	Nebulization flow rate			
	6 L/min	8 L/min	10 L/min	12 L/min
Solution fill volume: 2 ml				
Bird	54.4	62.0	57.2	58.4
DeVilbiss	55.6	60.4	56.0	65.6
Inspiron	58.4	65.2	68.0	68.0
Upmist	64.4	58.0	58.0	58.0
Solution fill volume: 4 ml				
Bird	59.2	65.6	58.0	64.0

volume output per unit time, and 2) neglecting the change in solution concentration as discussed previously. The delivery efficiency of the nebulizer can be expressed simply as

$$E = \frac{M_p - M_d}{M_p} \quad (9)$$

where E represents the nebulizer delivery efficiency, M_p is the drug amount loaded into the nebulizer before nebulization, and M_d is the drug amount left in the nebulizer after the nebulization. Nebulizers are often operated until there is no visible aerosol or “sputtering,” and a significant reduction in the nebulizer output occurs when the solution volume in the nebulizer reservoir becomes so low that it fails to maintain a continuous liquid supply to the nebulizer orifice. However, these are very crude measures and provide no indication of the amount of aerosolized drug a patient inhales.

The delivery efficiency, or the nebulizer output, can be expressed in many different ways, as widely documented in the literature. Sometimes it is represented as the volume output, or solution mass output. However, it is more practical to use the drug mass emitted from the nebulizer at or near the mouthpiece to estimate the nebulizer output, because the amount of aerosolized drug mass at this point in the system is the best measure of how much drug the patient has available to inhale.

Nebulizer output depends mainly on three variables: the type of the nebulizer, the operating conditions during nebulization, and the solution to be nebulized. Although solution density and viscosity play minor roles in nebulizer output for the majority of aqueous formulation, viscosity becomes an issue when aerosolizing highly viscous solutions. For any given solution and nebulizer, the operating pressure primarily determines the nebulizer output. Increasing the nebulization pressure usually increases nebulizer output. Increasing nebulizer output typically has a clinical benefit: it can reduce the time required to nebulize an effective dose, particularly for young patients who are less tolerant of the treatment procedure. As drug mass delivered per unit time is increased, treatment time is reduced leading to better acceptability and improved clinical outcome (27). Fig. 5 correlates drug mass output as a function of operating pressure (28).

A Pari LC Plus jet nebulizer (Fig. 6) was used in the study. The nebulizer was operated using a specially designed electronic unit to regulate the compressed air supplied to the nebulizer. The nebulizer was operated in a pulse mode, in which the time of nebulization was set at 3 s for each aerosol generation. The drug output was generally

Fig. 5 Emitted dose per generation from the nebulizer vs. the nebulization pressure. (Adapted from Ref. 28.)

greater with each incremental increase in operating pressure. These increases were significant ($p < 0.05$) over a range of nebulization operating pressures of 27–45 psi. Additional increases in operating pressure of 45 to 60 psi did not significantly increase aerosol drug output.

Finlay et al. (29) recently tested 15 different jet nebulizers available commercially to investigate the performance of nebulizers. The drug compound used in the study was a 2.5 ml unit dose of Ventolin® (containing 1 mg/ml of salbutamol sulfate), which corresponds to a 2.5 mg in nominal dose per drug container. Table 3 shows the experimental results for the different nebulizers.

Nebulizers fitted with a T-mouthpiece have an unrestricted flow of ambient air passing through the nebulizer output, supplying inhaled air flow, which effectively increases drug output. In vented nebulizers,

(Adapted from Ref. 29.)

the inhaled air must flow through the droplet production region. Therefore, the breathing pattern of the patient has an effect on the aerosol characteristics produced by such devices. The delivery efficiency of the commercial nebulizers tested ranged from 6 to 30% of the nominal dose loaded into the nebulizers. For conventional nebulizers, the inhaled dose is approximated by the amount of drug leaving the nebulizer divided by 2, since inhalation is assumed to occupy half of the breathing cycle (29). However, this remains a very crude measure of delivered or inhaled dose.

The importance of particle size distribution in determining the site of the deposition of pharmaceutical compounds within the respiratory tract has been discussed extensively in the literature (1–7, 10, 12, 20, 24, 27, 30). For any given inhaled dose of aerosolized drug, the particle size distribution of drug aerosol, aerosol velocity, the breathing pattern (inspiratory flow and volume), and lung morphology, determine the location the aerosol is deposited in the respiratory airways. It is generally well accepted that the particle size of drug aerosols generated for inhalation should be within 1–5 μm in diameter. Because of polydispersity of the aerosol, the mass median aerodynamic diameter (MMAD) and geometrical standard deviation (GSD) are often used to describe the distribution of aerosol particles. The MMAD is defined as the mass median of the distribution of mass with respect to aerodynamic diameter (1). The mass median diameter

(MMD) and GSD of the salbutamol aerosol generated by 15 different nebulizers (29) are shown in Table 4, where $\text{MMD} = \text{MMAD}/(\text{density})^{1/2}$.

(Adapted from Ref. 29.)

The size distribution of aerosols generated using most commercial nebulizers is typically highly variable with somewhat large mean diameters. This not only results in poor transfer efficiency but poor and highly variable respiratory deposition patterns between and within patient populations.

Metered dose inhalers

Pressurized metered dose inhalers (pMDIs) have been widely used in the treatment of asthma and COPD. These devices are more popular than nebulizers and dry powder inhalers. The popularity of the pMDI has steadily increased since the 1950s due mainly to its compact and portable size, self-contained power source, and other rapid therapeutic effects in the use of bronchodilators. pMDIs appear to be simple to use, although this appearance is in fact deceptive. Many patients are not adequately trained to correctly use pMDIs or find it nearly impossible to effectively coordinate their breathing with the high velocity release of the aerosol. High ejection velocity of the aerosol at the mouthpiece (usually near 30 m/s) is the single largest deficit of pMDIs. At these high ballistic velocities, most of the drug aerosol impacts in the mouth or throat and can not be readily entrained within the respiratory flow (even when coordinated with aerosol release). Typically, about 60–90% of the emitted drug will be deposited in the oral-pharyngeal region. This not only reduces the amount of drug that reaches the intended action site, but often contributes to unwanted systemic side effects due to oral absorption. Spacers have been developed that help mitigate this problem. The spacers are placed in front of the pMDIs actuator to reduce the aerosol velocity, and reduce the number of large diameter droplets before entering into the airway. However, this occurs at the expense of delivery efficiency, further reducing the dose of drug inhaled.

A typical pMDI consists of a drug reservoir containing the drug compound suspended or solubilized in liquefied propellant, a metering valve, and an actuator that connects with the metering valve through a stem. The propellants historically have been chlorofluorocarbons (CFCs) which

have high vapor pressures and are generally biologically inert. The pMDI delivers a metered dose of active drug compound using the propellants as a power source. In the rest position, the metering chamber is connected with the formulation reservoir. Depressing the drug canister activates the metering chamber and the formulation reservoir is then closed. Simultaneously, a connection is opened between the valve stem orifice and the metering chamber. The formulation contained in the metering chamber quickly escapes through the stem valve and spray orifice, atomizing the formulation. As the liquid CFCs vaporize, they generate sufficient energy to produce efficient two-phase atomization, without the need for an external power source (7).

The primary factors that will influence the performance of the pMDI are the propellant used, the physical properties of drug formulation, which partially governs droplet formation and drug uniformity, and the device itself.

Propellants: The propellants used in the pMDIs consist of CFCs with different molecular formulas. The propellants commonly used in inhalers to disperse the liquid into aerosols are CFC-11 (CCl_3F), CFC-12 (CCl_2F_2), and CFC-114 ($\text{CClF}_2\text{-CClF}_2$) (31, 32). These three propellants have been used for decades in pMDI products because of their unique properties, which include low toxicity, excellent physical and chemical stability, ideal vapor pressure, and generally good compatibility with drug compounds and surfactants. These propellants possess an appropriate degree of solvency that solubilizes the surfactants typically used in pMDI systems such as oleic acid, sorbitan trioleate, and soya lecithin, yet dissolve low quantities of most drugs. This combination of surfactant solubility and drug insolubility in the pMDI formulation is essential for maintaining uniform suspensions of appropriate particle size. The physical properties of these three propellants are shown in Table 5.

The vapor pressure of the formulation in a pMDI can be adjusted to a targeted value by mixing propellants with different vapor pressures. Propellants offer the additional advantage of having a narrow density range that may be adjusted to balance the density of the drug particle in suspension (33).

Table 5 Physical properties of CFCs propellants commonly used in pMDIs

Propellants	Molecular weight	Density (g/cm ³) at 21°C	Vapor pressure (psig) at 20°C	Boiling point (°C) at 1 atm	Atmospheric life (years)
CFC-11	137.4	1.49	−1.8	23.8	75
CFC-12	120.9	1.33	67.6	−29.8	111
CFC-114	170.9	1.47	11.9	3.6	200–300

Morén (32) investigated the influence of vapor pressure on the characteristics of aerosols generated using pMDIs. In these studies, nine healthy volunteers inhaled eight doses at one-minute intervals coordinated with the dose firing, and the amount of drug deposited in the actuator, extension tube, and mouth was determined spectrophotometrically. It was found that an increase in vapor pressure results in higher initial velocity of the aerosols, smaller initial aerosol particle size, and more rapid propellant evaporation. The amount of drug deposited in the actuator increased at the higher vapor pressure of 502 kPa, which was likely due to the high velocity of the aerosol exiting the spray nozzle and a wide spray angle.

Aerosol formation: Aerosol formation from pMDIs is a complex process influenced not only by the propellant as discussed above, but also by properties of the formulation and device design (e.g., valve volume and orifice size). After aerosol droplets form at the exit of the spray nozzle, an aerosol plume begins to expand, and large particles travel along the axis of the actuator. Fig. 7 shows photographs of aerosol formation using a commercially available pMDI.

Most large droplets fall out from the aerosol cloud, and those droplets are deposited in the mouthpiece or in the oral-pharyngeal region of the respiratory airways when the inhaler is used by a patient. When spacers are used, many large particles are collected within the spacers. The remaining aerosol cloud continues to evaporate, and the

velocity of the aerosol reduces dramatically from about 35 m/s at 5 cm from the spray orifice to about 10 m/s at 20 cm (34). During aerosolization, surfactant molecules, used as dispersing agents and valve lubricants, will influence the evaporation rate of the propellants (33). The dimension and shape of the aerosol cloud significantly influence the transport efficiency of aerosol to the respiratory tract.

Physical stability of drug suspension: The physical stability of the nonpolar drug suspensions formulated in pMDIs again depends on many parameters, such as propellant type, chemical properties of the drug compounds, and the surfactants used in the formulation. A suspension is a liquid system in which insoluble solid particles are dispersed in a liquid medium. Suspensions can be divided into colloidal suspensions, in which the solid particles are less than 1 μm , and coarse suspensions, where particles are larger than 1 μm (35). The physical stability of a suspension can also be classified according to whether the formulation is flocculated or deflocculated. In a deflocculated system, the solid drug particles settle down slowly and form irreversible aggregates. As a result the particles form a distinct cake on the bottom of a container. The deflocculated system is impossible to redisperse by simple shaking, and the suspension is unlikely to be of use after caking. Therefore, it is necessary to develop the flocculated formulation systems for pMDIs. In flocculated systems, the particles form large aggregates, so that the

Fig. 7 Formation of the aerosol plume as a function of time. Each frame has a time interval of 30 mins.

solid particles can be resuspended upon shaking. The formulation of a flocculated system requires reducing or neutralizing the zeta potential around the drug compound. This means that repelling forces between the particles are neutralized and the particles can then interact with each other to form large aggregates which rapidly settle but, can be easily redispersed (36). In formulating a suspension for pMDI use, the drug particles are usually less dense compared with the suspension media. Therefore, in an unshaken inhaler the drug gradually separates as a layer, which floats on the propellant and surfactant mixture, and is resuspended immediately after shaking. The solubility of the drug compound in the propellant also plays an important role in the physical stability of the pMDI formulation. An extremely low solubility of drug compound is required in the nonpolar system. Therefore, pMDI formulations usually require a polar salt to be incorporated, because significant drug solubility in the propellant can lead to crystal growth, often associated with the caking of the suspension and a reduced amount of fine particles (37).

Sedimentation ratio is often used to assess suspension stability. Byron (37) reported the sedimentation ratios for a 1% sodium fluoresein suspension formulation with different amounts of surfactant (sorbitan trioleate) after standing for 20 days at room temperature. The suspension formulation with the lowest sedimentation ratio had the best-flocculated system. However, all formulations were easily redispersible: one complete revolution of the container was sufficient to produce a homogeneous dispersion. There was no clear difference in the times taken to reach apparent sedimentation equilibrium. Physical stability of the formulation was determined according to:

- Whether the drug material was adequately deaggregated during manufacture,
- Whether redispersibility was easy and allowed doses to be metered reproducibly,
- Surfactant concentration-drug combination gave the greatest respirable fraction of the aerosols (37).

Determination of dose and particle size distribution:

The amount of drug reproducibly delivered from pMDIs per actuation is one of the most frequently reported performance parameters of these products. Several experimental configurations are used to characterize the pMDI's emitted dose. One of the most commonly used experimental protocols is described in the Official Compendia of Standards published by *U.S. Pharmacopeia* (38). The pMDI device is fitted with a sampling tube at one end, and a vacuum pump is connected with a filter holder at the other end. A continuous airflow is

drawn through the sampling tube to avoid the loss of the drug material into the atmosphere. The active compound delivered from the pMDI is recovered from the filter and the sampling tube to determine the mass output from the device. There are no universal definitions for different terminologies used to express dosages provided by pMDIs, and the labeling requirements for pMDIs differ among nations (37). In the United States, the emitted dose (label claim) is defined as the amount of drug leaving the device, excluding the drug mass left in the actuator and valve stem of the device. However, in other nations, the metered dose is often used, which includes the amount left in the actuator but not that retained in the valve stem (37). Descriptions of the emitted dose often use different terms, which are often used for different purposes (39, 40). Because of the lack of consistency in the terminology used in the literatures and by regulatory agencies, it is often difficult to compare the experimental results between different research groups, devices, and experimental methods and procedures. Therefore, it would be beneficial to harmonize the terminology commonly used to describe drug doses from different parts of the pMDIs, and efforts are currently underway to standardize the way delivered dose and device performance are measured and reported. Table 6 shows the definitions for the various doses frequently used in the literatures.

However, even with a clear understanding of the dose delivered by a pMDI, there is no direct or consistent correlation to the amount of drug delivered to the patient's lungs. A typical drug distribution within patients and from devices is shown in Table 7 (41). The table is based on an experiment conducted on healthy volunteers with an average FEV₁ at 105% of predicted (range 92–119%). A terbutaline formulation was labeled with ^{99m}Tc and administered to patients using a pMDI. The average inspiratory flow rate was 33.8 L/min, (SD = 6.7), and the total inspired volume averaged 2.86 L (SD = 0.87), with an average of (SD = 0.7) 9.1s breath-hold. The inter-subject variability in the patients' breathing patterns was relatively small, contributable to on-line monitoring of breathing patterns using a spirometer.

The amount of drug deposited in the lungs expressed as percentage of emitted dose (including drug left on actuator) was about 16.7% (SD = 9.6), and the percentage of emitted dose deposited in the oral-pharynx was 68.3% (SD = 10.2). The percentage of emitted dose deposited in the actuator was 13.4% (SD = 2.1). The intersubject variability for the percentage of emitted dose found in the actuator and oral-pharynx was 15.3 and 14.9%, and the variability for the total lung deposition was 57.7%. These

Table 6 Definition of various doses

Terminology	Description
Nominal dose (metered dose)	The dose represents the actual amount of the drug loaded into the pMDI device. It can be calculated using drug concentration times the metering valve volume.
Emitted dose (ex-valve dose)	The amount of drug emitted from the device, including the drug deposited on the actuator and inhaled dose.
Inhaled dose (label claim)	The amount of drug emitted from the device, not including the drug left on the actuator. This amount of drug is available for inhalation by patient.
Fine particle dose	The amount of drug with particle diameter less than 5.0 μm , which is a portion of the inhaled dose.
Deposited dose	The amount of drug deposited in the respiratory airways, which can further be divided into the drug amount in the oropharyngeal region and lungs.

large variations in the total lung deposition are typical of clinical results when inhaled drugs are given using pMDIs.

The particle size distribution of drug aerosol generated from the pMDI is another important performance parameter of the drug delivery device, which depends on the combination of the propellants and surfactants, the original size of the drug particle, and the design of the device (metering valve, orifice, actuator). The initial atomization process and subsequent spray evaporation govern the amount of drug aerosol deposited both in the oral-pharyngeal and pulmonary regions. Aerosol particles ejected from the pMDI experience constant changes in size due mainly to the drug formulation. Fig. 8 shows the change in particle size as a function of the distance from the actuator orifice. The experiment was conducted using a pMDI obtained commercially, and a laser diffraction instrument (Malvern, Mastersizer X) was used to determine the size of drug aerosol. The device was

mounted on a platform, and the distances between the actuator and the center of the laser beam were chosen to be about 5, 10, 15, 20, and 25 cm. The pMDI was operated according to the instructions given by the manufacturer, and five measurements were repeated for each chosen distance.

The size of the drug particle was about 8 μm at 5 cm between the actuator orifice, and gradually decreased to about 2.5 μm at 35 centimeters from the actuator orifice due to the evaporational shrinkage. The particle diameter was about 6.5 μm at a distance of 10 centimeters, which was about the distance to the oral-pharyngeal region from the actuator orifice. The amount of drug deposited in the oral-pharyngeal region is mainly due to the inertial impaction; therefore it depends more on particle size than on particle velocity. The inertial impaction is proportional to the square of the particle diameter, and is linearly proportional to the particle velocity. The decreases in particle diameter followed exponentially with the distance

Table 7 Deposition of radioactive drug after inhaling via pMDI

from the actuator orifice. The exponential decrease rate of particle diameter differs with different drug formulations (vapor pressure, nonvolatile concentration, etc.).

High Frequency Oscillating Devices

Ultrasonic nebulizer

Ultrasonic nebulizers utilize high frequency sonic energy to convert liquid drug formulations into aerosol clouds. Although these devices have been used in clinical settings since the 1960s, they are not as widely used as the jet nebulizer and pMDIs. Ultrasonic nebulizers typically have higher drug mass output and significantly larger particle size distributions at the point of aerosolization compared with jet nebulizers (42). Advantages and disadvantages of the ultrasonic nebulizer for the delivery of pharmaceutical compounds to the human respiratory airways are listed in Table 8. The output of drug compound leaving the ultrasonic nebulizer is at a relatively slow velocity compared with the jet nebulizer. Therefore, less patient coordination is required during treatment.

The reservoir temperature in the ultrasonic nebulizer increases rapidly during operation. In the study by Phipps et al. (20), the solution in the nebulizer increased from room temperature (~23°C) to greater than 30°C after

about 5 min of operation, and exceeded 40°C after 30 min of nebulization. This significant temperature increase may cause some pharmaceutical compounds to be degraded during aerosolization (43). Changes in drug potency due to delivery by ultrasonic nebulizer have been reported in the literature, with degradation more profound for protein and peptide therapeutics compared to more stable small molecules.

Mechanism of aerosol generation: Ultrasonic nebulizers generate aerosols using a piezoelectric transducer that vibrates when subjected to high-frequency electric energy. When liquid is fed continuously through or over the vibrating surface, a wave pattern is formed as the liquid spreads over the liquid surface. Liquid droplets are formed when the amplitude of the vibrating surface increases to the point at which the capillary wave becomes unstable and collapses (44). An empirical equation to calculate the droplet diameter (*D*) produced from an ultrasonic nebulizer was described by Lang (44). The diameter is approximately proportional to the capillary wave length (λ), density (ρ) and surface tension (σ) of the liquid, and the excitation frequency (*F*).

$$D = 0.34\lambda = 0.996 \frac{\sigma}{\rho F^2}.$$

(10)

As with jet nebulizers and pMDIs, the formulation characteristics include liquid density, surface tension, viscosity, and vapor pressure. Many of these that effect nebulizer performance of formulation properties are described in the above equation. The configuration of the device, such as the location of the baffles, mechanisms in the transport of the liquid formulation to the piezoelectric transducer, and the size of medication chamber, also affect the performance. The units frequency and amplitude of vibration, control the mass output and the particle size distribution permitting some adjustment in aerosol characteristics.

Performance characteristics: Greenspan (42) summarized the performance of commonly used ultrasonic nebulizers. The excitation frequency ranged from 1.3 to about 2.6 MHz, and the MMAD of the produced aerosols

Table 8 Characteristics of ultrasonic nebulizer

Advantages	Disadvantages
Little patient coordination	Large particle size and less efficient
Aerosol exited with low velocity	Microbiological contamination risk
Small dead volume and quite operation	Possibility of degrading drug compound
High dose output and fast drug delivery	Poor portability and is expensive
No propellants requirements	Requirement of electric power supplier

was approximately 1–7 μm . Several ultrasonic nebulizers generated relatively large aerosol particles, which were usually associated with low excitation frequency. Hager et al. (45) characterized the performance of two ultrasonic nebulizers using a pentamidine solution, which is used to treat *Pneumocystis carinii* pneumonia associated with acquired immunodeficiency syndrome (AIDs). The ultrasonic nebulizers used in the study were Fiso Neb (model FZV 40 BAMKI, Fisons) and Porta-Sonic (model 8500GB, Devilbiss). It was found that the mass output for FISO Neb at airflow rate of 6 L/min were 201.4 and 36.7 mg for drug concentrations of 50 and 10 mg/mL, respectively. Corresponding outputs decreased to 85.2 and 23.6 mg for Porta-Sonic nebulizer. However the MMD of aerosol generated from the Fiso Neb was 5.8–6.93 μm , and 1.96–3.04 μm for Porta-Sonic nebulizer. The higher mass output from the Fiso Neb compared to the Porta-Neb was due to the presence of larger aerosol particles produced by the Fiso Neb nebulizer. However, these larger droplets are typically nonrespirable, if they are transported at all to the patient inhalation port. Therefore, the overall dose efficiency of ultrasonic nebulizers tend to be poorer than jet nebulizers.

ADVANCED DRUG DELIVERY TECHNOLOGIES

Using the various drug delivery devices, such as pMDIs, nebulizers, and DPIs, discussed in the first half of this chapter, has had an enormous impact on patient quality of life, as inhaled drugs play an important role in the management of airway diseases. However, past successes in topical delivery of drugs to the lung owe more to the therapeutic properties of the drugs used than to the delivery device itself (30). Currently used delivery devices tend to be inefficient, with small amounts of drug delivered to the site of action, with a large portion of the drug compound lost in the device or deposited orally, often causing unwanted side effects.

The shortcomings described for the current devices limit their ability to meet the demands created by advancements in more potent small molecules and biotechnology therapies. More and more new drugs are potential inhalation candidate therapies to treat various diseases, including nonairway diseases such as diabetes. There is an urgent need for more advanced drug delivery technology, which can deliver the drug more precisely to the targeted area for action, with better efficiency and improved reproducibility. Over the last 10 years, many innovations have occurred in the field of inhalation drug delivery with advances in aerosol technology and electronics, spurred by the demand created by new drug

compounds. Most of the technologies have tried to tackle problems such as reducing the ballistic velocity of aerosol released from pMDIs by breath activated functions and developing new propellants with lower ejection pressures. Focus has shifted to defining and developing a more “ideal” inhaler to administering various pharmaceutical compounds for different diseases. The following describes many of the features these new pulmonary drug delivery devices are designed to include (30).

- Aerosol generation independent of the patient's inhalation.
- Duration of aerosol dose generation should occupy a substantial part of a slow inhalation cycle. A generation time of greater than 1 s will permit the patient to better coordinate aerosol delivery effectively during inhalation.
- The aerosol cloud should consist largely of particles of less than 5 μm in size. Fine aerosols are necessary for delivery to the lung periphery if this is the site of action or if systemic delivery is the objective. The ability to vary and then control the mean particle size distribution of the aerosol would be an added advantage for targeting deposition within different regions of the respiratory tract.
- The velocity of the aerosol should be minimal to reduce oral-pharyngeal deposition and provide maximum delivery to the lungs.
- The inhaler should be simple to use, require little patient coordination and preferably should be breath-actuate.
- The inhaler should have dimensions similar to those of the pMDIs, fitting the pocket or the handbag and permitting discrete use.
- The inhaler should contain a large number of doses (>50 doses).
- A dose counter should be included.
- The device should be easy to manufacture and reasonably priced.
- The device should generate uniform doses throughout its life, be resistant to microbial and other contamination, and have a suitable shelf life.
- Propellants should be avoided, or designed for low environmental impact.

Pressure Driven Devices

New generation pressurized metered dose inhaler

Asthma affects an estimated 100 million people worldwide, including over 15 million in the United States (45), and while the pMDI has many disadvantages, it still is the most prescribed drug product for the treatment of asthma. The long-term dominance of pMDIs in inhalation drug

Table 9 Physical properties of propellants (CFCs and HFAs)

Propellants	Density (g/cm ³) at 21°C	Vapor pressure (psig) at 20°C	Boiling point (°C) at 1 atm
CFC-11	1.49	– 1.8	23.8
CFC-12	1.33	67.6	– 29.8
CFC-114	1.47	11.9	3.6
HFA-134a (replace CFC-12)	1.21	81	– 27
HFA-227 (replace CFC-12, CFC-114)	1.41	43	– 17

delivery is mainly due to its convenience. However, it is extremely difficult to use effectively. Everard (46) pointed out that the pharmaceutical industry elected to perpetuate the failings of the pMDI and develop replacements for CFCs, rather than develop novel devices to meet current demands. Extensive resources have been invested to preserve the pMDI when the industry was challenged with phasing out CFC propellants, and to reduce the oral-pharyngeal deposition by methods such as using attached spacers and breath-actuated devices.

pMDIs with new propellants: Since 1974, the CFCs have been believed to contribute to erosion of the earth's stratospheric ozone. Coyne (47) summarizes the history and progress of the Montreal Protocol negotiations and formation in great detail, and introduces the objectives and history of the Pharmaceutical Aerosol CFC Coalition (PACC) in the United States and the International Pharmaceutical Aerosol Consortium (IPAC) in Europe. The objectives of the organizations are to find replacements for CFC propellants that can be used in pMDIs.

Reformulation of drugs used in pMDIs to avoid CFC propellants presented numerous obstacles, because no approved alternative pharmaceutical propellants were available (48). Replacement of the propellants used in pMDIs requires changes in many fundamental aspects of formulation, device design, device components, and manufacturing. Several classes of propellants have been considered as alternatives for use in pMDIs, but each has its disadvantages, as shown below, in a listing based on Leach (49).

Alternative propellant	Disadvantage(s)
Dimethyl ether	Flammable
Hydrocarbons	Flammable, high volatile organic compound content
Hydrochlorofluorocarbons	Some ozone depleting potential
Compressed gases (e.g., carbon dioxide and nitrogen)	Inconsistent pressure throughout the product life

So far, two alternative propellants, tetrafluoroethane (HFA-134a, CF₃CH₂F) and heptafluoropropane (HFA-227, CF₃CHFCF₃), have been successfully tested and developed as propellants in pMDIs. The physical properties of these two propellants are compared with those of CFCs in Table 9.

There are many similarities between pMDIs formulated with CFCs and HFAs, such as the operating principles and basic components. However, due to differences in the physical properties such as vapor pressure, density, and solvency characteristics, the pMDIs powered with HFA propellants encounter complex formulation challenges and the need for new hardware designs. The surfactants commonly used in the CFC-based pMDIs are oleic acid, sorbitan trioleate, and soya lecithin, which not only help to stabilize the formulation, but also help lubricate the metering valve system. These surfactants exhibit lower solubility when formulated with HFAs compared to CFCs. Therefore, sometimes a co-solvent will be added to the HFA formulation. New surfactants may need to be identified for drug formulations when using HFAs as propellants. However, with each change in product formulation, extensive testing is required before the product is approved for general clinical use.

Therefore, the phasing out of CFCs in pMDIs has provided an opportunity to improve the performance of the pMDIs and address the shortcomings of pMDI technology. Keller (50) compared the performance of three different active compounds, beclomethasone dipropionate (BDP), budesonide, and di-sodium-cromo-glycate (DSCG), formulated with both CFC and HFA propellants. The HFA formulations were compared with three types of commercial devices, Becotide 100®, Pulmicort®, and Intal®. The amount of drug deposited on the mouthpiece and USP throat was measured, and particle size distribution and fine particle dose were also determined accordingly. Table 10 compares the performance of the pMDIs using formulations with CFCs and HFAs propellants.

Table 10 Performance of pMDIs formulation with CFCs and HFAs

Product batch no. Formulation (label claim)	Becotide 100® 10072926 CFCs suspension (100 µg)	BDP 809/L86-04 Non-CFCs solution (100 µg)	Pulmicort® YK702 CFCs suspension (200 µg)
Mouthpiece (µg)	16.6	7.8	21.4
USP-throat (µg)	55.2	22.0	114.0
FPD (µg)	26.9	60.8	43.3
FPF (%)	26.9	60.8	21.7
MMAD (µm)	~3.1	~1.4	~4.5
GSD	1.63	1.87	1.63

Product batch no. Formulation (label claim)	Budesonide 821/372-05 Non-CFCs suspension (200 µg)	Intal® FEF2E CFCs suspension (1000 µg)	DSCG 802/352-01 Non-CFCs suspension (1000 µg)
Mouthpiece (µg)	33.4	419.3	116.8
USP-throat (µg)	46.7	385.7	488.4
FPD (µg)	86.2	147.8	300.0
FPF (%)	43.1	14.8	30.0
MMAD (µm)	~3.1	~4.0	~3.8
GSD	1.55	1.81	1.65

(Adapted from Ref. 51.)

For the BDP formulation, the fine particle dose increased from 27 to about 61 µg and the drug lost in the mouthpiece and USP throat was reduced from 17 µg and 55 µg to about 8 µg and 22 µg respectively, when using the non-CFC formulation. The increase in the fine particle dose resulted from the reduction in the MMAD, which changed from 3.1 to about 1.4 µm. The particle size distribution of a suspension formulation is expected to be controlled mainly by the drug powder particles used in the formulation. For a solution formulation, particle size distribution is dictated by other factors such as formulation and device configurations. The fine particle dose was also increased for the budesonide formulation associated with a decrease in the amount of drug deposited in the USP throat, and the particle size distribution of budesonide delivered from both pMDIs changed slightly since both formulations were suspensions. Similar results were achieved for the DSCG compared with the Intal pMDI, except that the increase in fine particle dose was likely due to the decrease in the drug amount deposited in the mouthpiece.

These performance changes typically reduce the drug deposition in the oral-pharyngeal region, providing an added advantage of producing fewer steroid side effects such as candida infection and hoarseness of the throat (49).

pMDIs with breath activated function: The firing of the pMDI and inhalation by the patient have to be

coordinated or “synchronized,” because the drug aerosol is produced by the pMDI for a very short time only, in the order of milliseconds. This presents a challenge for patients to inhale and capture the aerosol as it is generated. It has been estimated that more than half of the patients (47–89%) receive little benefit from their pMDIs because of failure to coordinate the firing of the pMDIs and inhalation (51,52). A breath-activated pMDI (Autohaler, 3M Riker) has been developed to minimize the need for the actuation-inhalation coordination. This device is intended to reduce the performance variability of the pMDIs caused by differences in use techniques. The Autohaler is triggered by the patient’s inhalation flow rate. To use the Autohaler, the patient turns a level on the top of the device that engages a spring mechanism to load the canister against a vane mechanism that is used between the canister and the actuator. When the patient’s inspiratory flow rate exceeds 30 L/min, the vane moves and allows the canister to be pressed into the actuator to deliver the drug.

Newman (53) conducted a clinical study to compare the performance of conventional pMDIs with the Autohaler using a scintigraphic technique to measure the drug deposition in the different sites of interest. The patients who participated in the study were divided into two groups classified as good coordinators and poor coordinators. Initially, patients used their own inhalers

Table 11 Percentage deposition at different sites

Deposition site	Own MDI	Taught MDI	Autohaler
Good coordinators			
Lungs	18.6 (2.9)	12.8 (1.8)	17.5 (2.8)
Oropharynx	64.4 (3.8)	71.1 (2.5)	61.2 (4.5)
Actuator	16.1 (2.0)	15.8 (1.2)	21.0 (2.8)
Exhaled	0.7 (0.4)	0.3 (0.1)	0.3 (0.1)
Poor coordinators			
Lungs	7.2 (3.4)	22.8 (2.5)	20.8 (1.7)
Oropharynx	67.7 (4.7)	59.3 (2.3)	60.7 (2.2)
Actuator	23.5 (3.8)	17.6 (0.9)	18.2 (1.3)
Exhaled	1.7 (0.9)	0.3 (0.1)	0.2 (0.1)

(Adapted from Ref. 53.)

as baseline deposition values. The depositions were then measured after those patients were instructed about the proper inhalation technique when using their own inhaler and after using the Autohaler. Table 11 shows the percentage of the aerosol dose located at various locations after inhalation by good coordinators ($n = 10$) and by poor coordinators ($n = 8$).

For the good coordinators, the deposition patterns were very similar for the patients using their own pMDIs and Autohaler, in which about 18% of the aerosol dose was deposited in the lungs and about 60% of the dose was deposited in the oral-pharyngeal region. There was a trend toward less deposition in the lungs after the patients had been taught the proper pMDI technique. It was possible that the patients had different abilities to familiarize themselves with the new technique as instructed during the study. There was a clear improvement in the lung deposition for the poor coordinators after they were given instruction or when they used the Autohaler, in which over 20% of the aerosol dose was deposited in the lungs. The increased lung deposition contributed to the improvement in the pulmonary function parameter, in which the FEV₁ increased significantly from the baseline.

New Pressure Driven Devices

Respimat™

The agreement to eliminate the use of CFCs in pMDIs for respiratory medication has stimulated interest in the development of propellant-free inhaled drug delivery technology. The Respimat developed by Boehringer Ingelheim (Ingelheim am Rhein, Germany) is one of the technologies under development (54–58). The device consists of a Uniblock, spring, drug cartridge with a capillary tube, and a nonreturn valve. The Uniblock is the major component of the device, which contains two nozzles positioned at opposing angles. The spring is the power source. Turning the lower part of the device, the rotation movement is transferred to a liner movement, which simultaneously tightens the spring and pushes the capillary tube with the nonreturn valve to the lower position. During this movement, about 13.5 μ l of drug solution is drawn through the capillary to a pump chamber. When the patients press the release button, the mechanical force stored in the spring pushes the capillary tube and nonreturn valve to the upper position, driving the metered volume of drug solution through the two jet nozzles in the Uniblock, which generates two jets of liquid. The two jets are directed toward each other at a carefully controlled angle, and aerosol is generated by the impaction of the two jets.

Newman (55) examined the deposition profiles in patients of several developmental Respimat prototypes using gamma scintigraphic techniques. In these studies, the deposition of the bronchodilator fenoterol and the corticosteroid flunisolide were examined. Fenoterol in the Respimat was formulated in an aqueous medium, and flunisolide was formulated in 96% ethanol. The experimental data from these studies are shown in Table 12.

The performance of the Respimat was clearly improved for the final prototype compared with Prototype III. Drug deposition in the lungs increased from approximately 31 to 39% for the fenoterol, and from about 40 to 45% for the drug compound of flunisolide respectively. At the same time, the oral-pharyngeal deposition decreased from

Table 12 Average deposition data using the Respimat (% of the emitted dose)

Device	Formulation	Lung deposition	Oropharynx deposition	Reference
Prototype III	Fenoterol (100 μ g, aqueous)	31.1	53.7	55
Prototype III	Flunisolide (250 μ g, ethanolic)	39.7	39.9	56
Final Prototype	Fenoterol (100 μ g, aqueous)	39.2	37.1	57
Final prototype	Flunisolide (250 μ g, ethanolic)	44.6	26.2	57

(Adapted from Ref. 55.)

Fig. 9 The schematic diagram of the AeroEclipse nebulizer. (Courtesy of Monaghan/Trudell International.)

approximately 54 to 37% for the fenoterol, and from 40 to about 16% for the flunisolide. Comparing the deposition data for the aqueous and ethanolic formulations, it can be seen that the ethanolic formulation had better performance, which may be due to the different particle size distribution for the formulations. The MMADs of the aerosols used in the Respimat were $2.0 \pm 0.4 \mu\text{m}$ for the aqueous formulation and $1.0 \pm 0.3 \mu\text{m}$ for the ethanolic formulation (53). The overall deposition efficiency of this device was apparently two to three times better than typically seen with pMDIs.

AeroEclipse™

The AeroEclipse (Monaghan/Trudell International) shown in Fig. 9, is a nebulizer powered by compressed air, which can be operated in both continuous nebulization and breath-actuated modes. The nebulizer was characterized,

Fig. 10 The metered dose liquid inhaler as shown in Aradigm Corporation’s website (www.aradigm.com).

in vitro, using different breathing patterns, with either continuous nebulization or breath-actuated nebulization (59). A piston pump was used to mimic a range of breathing patterns in pediatric patients.

Table 13 shows the experimental data. The average drug mass for the three breathing patterns were $11.1 \pm 0.74\%$ (P1), $22.9 \pm 2.74\%$ (P2), and $36.3 \pm 1.22\%$ (P3). The average mass median aerodynamic diameter was $3.55 \pm 0.07 \mu\text{m}$ with the geometric standard deviation of 2.55. The test was also conducted to compare the device performance with other small-volume nebulizers (60), and found to be more efficient in the delivery rate (mass out per minute) than that of other SVN’s.

AERx™

The AERx, developed by Aradigm (Hayward, CA), is a metered dose liquid inhaler designed to deliver various pharmaceutical compounds to the peripheral lungs. The system, as shown in Fig. 10, consists of a unit dose disposable container equipped with a nozzle array, a piston assembly, and electronics associated with breath actuation and compliance monitoring functions (61).

The unit dose package contains the unit dose reservoir and an array of laser drilled nozzles, and the reservoir and

Table 13 Breathing patterns

Pattern	Tidal volume (ml)	Breathing frequency (1/min)	Nebulization
P1	50	40	Continuous
P2	200	25	Continuous
P3	440	19	Breath-activated

(Adapted from Ref. 60.)

Table 14 Emitted dose (% of loaded dose) vs. inhalation flow rate ($n = 5$)

Flow rate (L/min)	Emitted dose (% loaded dose)
20	50.6 \pm 2.0
30	68.6 \pm 3.0
45	72.3 \pm 2.5
60	70.9 \pm 1.5
70	68.5 \pm 1.3
85	66.1 \pm 5.1
100	61.5 \pm 1.9

(Adapted from Ref. 61.)

nozzle array are connected with a heat seal that allows the formulation to flow from the reservoir to the nozzle after the seal is ruptured. The piston assembly consists of a motor, a piston, and a cam, which compresses the unit dose packet to extrude the drug under pressure through the nozzle array to produce aerosols suitable for inhalation. The AERx also has internal electronic monitoring, which measures the patient's inspiratory flow rate as a function of time of inspiration and triggers the dispensing of the dose at a predetermined inspiratory flow rate and time for optimal delivery. The dosage administered is also logged, thereby providing a record of treatments and an indication of patient compliance with therapy (62).

The performance of the AERx has been characterized both in vitro and in vivo (63–67). Schuster et al. (61) reported in vitro experimental data of emitted dose as a function of inhalation flow rates from 20 to 100 L/min, and Table 14 shows the emitted dose expressed as the percentage of loaded dose at different inhalation flow rates. The emitted dose was consistent at inhalation flow rates ranging from 30 to 70 L/min, which averaged approximately 60–70% of the loaded dose emitted from the device. The percentage of loaded dose emitted from the device was about 51% at the inhalation flow rate of 20 L/min. When the device was used at this low flow rate, the aerosol was not efficiently entrained into the air, which was confirmed by a large fraction of the drug compound recovered from the air channel opposite the nozzle (61). The emitted dose was also decreased with the increase in the inhalation flow rate, which may have been due to increase in turbulent deposition as explained by the authors.

A study was also conducted both in vitro and in vivo to compare the performance of the AERx with a pMDI device that was operated with a SmartMist™ system for in vivo study using the scintigraphic technique (64). Table 15 shows the in vitro experimental data for both the AERx and the pMDI devices.

Table 15 In vitro performance of solution MDI and AERx system

	Solution MDI ($n = 4$)		AERx system ($n = 4$)	
	Mean	SD	Mean	SD
Emitted dose (%) ^a	63.2	8.2	60.8	7.1
FPF (%) ^b	71.0	5.6	90.6	1.6
MMAD (μ m)	1.2	0.1	2.6	0.1
GSD	1.8	< 0.1	1.5	0.3

^aPercentage of radioactivity contained in the AERx dosage form or ex-valve dose for the MDI.

^bFPF = Amount of aerosolized radioactivity in droplets with less than 5.7 μ m.

(Adapted from Ref. 63.)

The in vitro data showed that the fine particle fraction for the AERx was approximately 91% of emitted dose compared with 71% for the pMDI at the comparable emitted dose. The mass median aerodynamic diameter was 2.6 μ m for the AERx and 1.2 μ m for the pMDI, with a slightly larger GSD. An experiment was conducted to compare the in vivo performance of both devices using scintigraphy (64). The average depositions (expressed as the percentage of loaded dose for the AERx and percentage of ex-valve dose for the pMDI) in the oral-pharynx and stomach were 6.9% with a relative standard deviation (RSD) of 47% for the AERx and 42% with a RSD of 16% for the pMDI respectively. The average depositions in the lungs were 53.3% (RSD = 10.9%) and 21.7 (RSD = 30.9%) for the AERx and the pMDI, respectively. The experimental data also showed that uniform drug distribution in the lungs was achieved while using the AERx ($c/p = 1.15$) as compared with that of the pMDI ($c/p = 1.66$), where the c/p ratio is defined as the ratio of drug deposition in the central region to that of peripheral region.

HaloLite™

HaloLite, shown in Fig. 11, is a hand-held drug delivery system developed by Medic-Aid (Bognor Regis, United Kingdom). The device, which uses compressed air, consists of a medication chamber, a control unit, and an aerosol generation assembly that is operated by a portable, dedicated compressor. The aerosol is generated based upon conventional nebulization principles. The control unit allows the patient to select a budesonide nebulizing suspension, salbutamol, or terbutaline, since the device is calibrated to deliver preset doses of 50 μ g of budesonide, 200 μ g of salbutamol, or 500 μ g of terbutaline from commercially available pre-mixed solution formulations

Fig. 11 The schematic diagram of the Halolite. (Courtesy of Medic-Aid.)

of each drug (68). The device has the capability to analyze the patient's breathing pattern (flow rate, frequency, etc.) to determine a) the aerosol pulse time for each inhalation, b) whether the patient is inhaling or exhaling, c) the start of inhalation, and d) trigger the aerosolization process.

In vitro experimental data show that the fine particle fraction ($<5.0\ \mu\text{m}$) ranged from 70 to 80% of the device output, and the coefficient of variation for the dose output was 6% at a preset dose of 63 mg of 1% NaF solution (69). The device was also evaluated in vivo using healthy volunteers and asthmatics, and the coefficient of variations were 11% for the healthy volunteers and 21% for the asthmatics.

New High Frequency Oscillating Devices

AeroDose™

The AeroDose is a battery-operated drug delivery device under development by AeroGen, Inc. (Sunnyvale, CA),

Fig. 12 The schematic diagram of AeroDose™ as shown in AeroGen, Inc.'s website (www.aerogen.com).

which uses vibrating orifice technology to produce drug aerosols suitable for human inhalation. The schematic diagram of the device and its operation principle are illustrated in Fig. 12. The device consists of a drug canister, aerosol generator assembly, and electronic control unit. The aerosol generator contains a dome-shaped aperture plate with 600 tapered holes that vibrate due to the attachment to a piezoelectric crystal. The piezoelectric material will undergo small physical displacement at ultrasonic frequency to generate aerosols with low velocity. During each use, a droplet of formulation ($\sim 15\ \mu\text{L}$) is dispensed from a multidose canister to an aperture plate by a metering pump, as shown in Fig. 12, and an aerosol is then generated by breath activation.

Three AeroDose devices were characterized to determine the in vitro performance using albuterol sulfate with a nominal dose of $120\ \mu\text{g}$ per actuation (70,71). The average liquid volume dispensed for three devices was 15.2 ml with a coefficient of variation (cv) of 2.7%. The emitted dose expressed as percentages of nominal doses were 80% (cv 5.9%), 81% (cv 3.7%), and 79% (cv 4.0%). The MMADs were $2.0\ \mu\text{m}$ (cv 13%), $2.0\ \mu\text{m}$ (cv 5.7%), and $1.9\ \mu\text{m}$ (cv 21%), with GSDs of 2.1 (cv 7.2%), 2.2 (cv 4.5%), and 2.4 (cv 4.7%) for the three devices tested. A lung deposition study using $^{99\text{m}}\text{Tc}$ radiolabeled albuterol sulfate was also conducted to determine the amount of drug deposited in the lungs for both the AeroDose and the conventional pMDI. The average lung deposition was 18% (cv 32%) of the emitted dose for the pMDI and 70% (cv 28%) of the emitted dose or an overall delivery efficiency of approximately 56% for the AeroDose for the six volunteers who participated in the study.

Metered solution inhaler (MSI)

The metered solution inhaler (MSI), under development by Sheffield Pharmaceuticals, uses the same aerosolization principle as the AeroDose. The MSI is a portable, hand-held drug delivery device, as shown in Fig. 13. Using a

Fig. 13 The metered solution inhaler as shown in Sheffield Pharmaceutical's website (www.sheffieldpharm.com).

motorized pump, drug solution is delivered to the surface of a ultrasonic horn powered by a piezoelectric crystal upon actuation, and is then aerosolized in about 1 s (72, 73).

The performance of the MSI was characterized *in vivo* using morphine sulfate for systemic absorption (72). A total of 1.25 mg of morphine sulfate was delivered in five doses of 250 μg per actuation to the healthy volunteers. The average amount of drug deposited was approximately 800 μg in the lungs and less than about 500 μg in the oral-pharynx; therefore the average respiratory deposition efficiency was approximately 64% of the inhaled dose. The average amount of drug deposited in the peripheral respireto region was slightly over 300 μg , a little less than 300 μg was deposited in the intermediate lung, and about 200 μg was deposited in the central region. The ratio of deposition in the peripheral to central regions ranged from 1.1 to 2.2. The morphine sulfate concentration in the plasma reached a peak within 3 min after inhalation, compared with 15 min for the subcutaneous injection. The peak plasma concentration level for the inhalation route was more than double compared to the subcutaneous route.

Vibrating membrane nebulizer

The vibrating membrane nebulizer is currently under development by Pari GmbH, (Germany), which is based

upon the TouchSpray technology developed by The Technology Partnership plc (United Kingdom). The main aerosol generation principle is similar to that of AeroDose, which uses piezoelectric material as a power source to vibrate a surface having on it a droplet of drug solution. The vibrating membrane nebulizer consists of two major components, a membrane and a piezoelectric ring, as shown in Fig. 14. The membrane is a circular, wafer-thin metal plate with small holes. A ring-shaped piezoelectric actuator excites the membrane to vibrate, thus ejecting the fluid through the holes as droplets and creating aerosols. Unlike the AeroDose, which is a single-dose device, the vibrating membrane nebulizer is a continuous generation device similar to the conventional nebulizer, which produces aerosols during both inhalation and exhalation (74, 75).

Experimental data obtained from *in vitro* testing using a functional model of the vibrating membrane nebulizer showed that the average percentage of emitted dose for a continuous aerosolization in approximately 8 min was about 79% of dose loaded in the device, and the output rate of the delivery device was found to be about 238 $\mu\text{g}/\text{min}$. The mass median diameter measured by the Malvern Diffraction Sizer was 4.6 μm . It was also found that the cumulative output from the device was linearly proportional to the time of aerosolization, which implied a constant output rate throughout the entire aerosolization process (75). Experimental data obtained from a prototype device developed based upon the functional model showed a reduction from 79 to about 50% in the emitted dose of the device. The amount of drug left in the device increased

Fig. 14 Hand-held EHD device being developed by BPT.

from 477 to about 1060 mg, which changed from 19 to 43% in terms of percentage to the loaded dose. The increase in the drug amount left in the device reduced the delivery efficiency of the device. The delivery efficiency can be improved by redesigning the flow channel and incorporating a breath-activated function to eliminate the aerosolization process during exhalation, as suggested by the authors (74).

Novel Electrohydrodynamic (EHD) Devices

Electrohydrodynamic (EHD) aerosolization is a process of the disruption of a liquid surface into a spray of droplets when subjected to an electric field. The liquid meniscus at the outlet of a capillary tube takes a conical shape under the action of the electric field. The cone tip breaks up into a spray of fine, charged aerosol (76). The cone-jet mode offers the appealing feature of aerosol monodispersity. It can produce droplets/particles over a wide size range, from submicron to hundreds of microns in size, depending on liquid flow rate, applied voltages, and physical and chemical properties of the liquid. When considering the size range of interest to pulmonary drug delivery (1–5 μm), the production of monodispersed aerosols with relative ease by EHD aerosolization technology is unmatched by any other aerosol generation process. Additionally, the aerosols are generated from capillary nozzles having relatively large diameters (e.g., 100 μm), which are therefore, unlikely to clog at the atomization site or during the metering of each dose. When considering the particle size range of 1–5 μm , the capacity to produce monodispersed aerosols with relative ease by EHD is also unmatched by any other aerosol generation process (77). The particle size distribution of the aerosol can be controlled by adjusting a number of variables, such as physical and chemical properties of drug formulations, operating conditions, and electric field. Another key clinical and technical attribute of the EHD technology is that it delivers a soft (isokinetic) aerosol cloud of nearly monodispersed particles to the patient, because aerosol formation does not require any liquid propellants or other pressurized systems. The EHD process can aerosolize a broad range of drug formulations, requires low precision manufacturing (i.e., low-cost production), and is amenable to miniaturization. These fundamental features underpin the ability of EHD pulmonary drug delivery devices to aerosolize a wide array of drug formulations, and provide accurate, reproducible drug delivery with targeted dosing to the human respiratory tract. Battelle Pulmonary Therapeutics, Inc. (BPT) is currently developing an array of EHD pulmonary devices, ranging from small hand-held

disposable units, home table-top aerosol delivery devices, to large benchtop clinical devices designed to operate continuously with high outputs (Fig. 15).

In vitro performance

Prior to clinical evaluations, comprehensive studies were conducted to characterize prototype EHD pulmonary drug delivery devices for emitted dose uniformity and reproducibility of particle size distribution (78). Table 16 shows the dose uniformity. The nominal dose is defined as the amount of active drug metered as a liquid solution from the device. The emitted dose is the amount of aerosolized drug obtained at the exit of the mouthpiece, and the device delivery efficiency is the ratio of the emitted to nominal dose. The mean delivery efficiency was approximately 94% (SD = 3.2) with a 3.4% coefficient of variation. The delivery efficiency for the two devices tested was 93% (SD = 3.60, $n = 5$) and 95% (SD = 2.8, $n = 5$), respectively. The intradevice variation was 1.7% (coefficient of variation, $n = 2$ prototypes). There were no significant differences ($p > 0.05$) in the drug mass output within the device throughout its life cycle, nor between devices tested in the study.

Fig. 15 shows the drug mass recovered from the various stages of the impactor and device at a nominal drug dose of 75 μg per actuation. The amount of drug deposited on each stage was used to calculate the MMAD and GSD. The calculated MMAD was 2.85 μm with a GSD of 1.6. The fine particle fraction (FPF) of the aerosol was 90% (<5.8 μm) of the emitted dose, and 95% (<5.8 μm) of the dose distal to the USP throat.

In vivo performance

A Phase I clinical study was conducted to evaluate the performance of the prototype EHD pulmonary drug delivery device in healthy volunteers (78). The EHD

Fig. 15 Particle size distribution of a NCE from EHD device. (Adapted from Ref. 78.)

Table 16 Dose uniformity of a NCE delivered EHD pulmonary drug delivery device

Device ID	Actuation number	Nominal dose (µg)	Emitted dose (µg)	Device delivery efficiency (%)
Device 1	3	75	74.2	98.9
	15	75	68.5	91.3
	30	75	69.1	92.1
	45	75	67.8	90.4
	60	75	67.8	90.4
Device 2	3	75	71.3	95.0
	15	75	67.8	90.4
	30	75	73.4	97.9
	45	75	71.7	95.6
	60	75	71.7	95.6
Mean			70.3	93.7
SD			2.42	3.22
CV(%)			3.44	3.44

(Adapted from Ref. 78.)

device was compared with a commercially available capsule dry powder inhaler (DPI). The NCE was prepared in two formulations. The first was a powder formulation specific for the DPI, and the second was formulated in a liquid solution for the EHD device. Each formulation was radiolabelled with ^{99m}Tc, and the amount of drug deposited in the lungs from each device was quantified using gamma scintigraphy. Each volunteer was administered one dose of drug using the DPI and three different doses using the EHD device. The nominal doses were 1000 µg for the DPI and 150, 250, and 400 µg for the EHD device. Multiple blood samples were collected from each subject up to 8 h after dosing to measure plasma drug

concentration. An interval of 1 week was used between administration of the four doses.

The average whole lung deposition efficiency for the EHD device expressed as the percentage of the emitted dose was approximately 78% (cv 7.3%) for the 400-µg dose.

Fig. 16 shows representative scintigraphic images from both the DPI and the EHD pulmonary drug delivery device. It can be seen that the EHD pulmonary drug delivery device produced a uniform deposition distribution through the lung field with only ~16% deposition in the oral-pharyngeal region, and virtually no drug in the GI tract. However, the amount of drug

Fig. 16 Scintigraphic images of the EHD device and the DPI. (Adapted from Ref. 78.)

Table 17 Performance comparison of various devices

Delivery system for liquid	System features	Particle size	Device efficiency	In vivo deposition
RespiMat	Mechanical spring	3.5–6.5 μm		30–45% of emitted dose
AeroEclipse™	Compressed air powered	~3.6 μm	11–36% of nominal dose	
AERx	Mechanical, battery powered	2–4 μm	50–72% of nominal dose	~53% of loaded dose
Halolite	Compressed air powered	~3.0 μm		8–10% of nominal dose
AeroDose	Vibrating orifice	~2.0 μm	~80% of nominal dose	~70% of emitted dose
MSI™	Vibrating orifice	FPF >50% of emitted dose		~64% of emitted dose
Membrane nebulizer	Vibrating orifice, continuous mode	NA	50–80% of emitted dose	NA
EHD	Electrospray	2–4 μm , adjustable	~93% of nominal dose	~78% of emitted dose

deposited in the oral-pharyngeal region using the DPI averaged 67% of metered dose, which was nearly 6 times higher compared with that of the high dose delivered using the EHD device. The AUC for plasma drug concentration with the DPI was approximately 20% higher than that of the EHD device for a comparable deposited pulmonary dose. It appeared that the higher systemic exposure resulting from the DPI was likely due to absorption from the throat and GI tract.

Performance Comparisons

Comparison of the performance of various drug delivery devices based upon the data published in the literature is often difficult because of inconsistency in the experimental methods used in the characterization of those devices as well as differences in the devices. However it is also extremely important to understand the different features of the devices to help select the best device for a drug compound intended for delivery through the human respiratory tract. Table 17 summarizes the performance of devices currently under development.

The selection of a drug delivery system suitable for the administration of a particular drug compound to human respiratory airways depends not only on the device performance, but also on many other factors such as drug properties, formulation excipient, intended site of action, marketing preference, and regulatory requirements. It is important to fully understand the drug properties during the formulation development so that a proper excipient system can be identified. The

selection of an excipient for a particular drug also influences the particle size distribution of aerosol generated from a drug delivery device. For example, increasing the volatile components in the solution formulation can reduce the diameter of aerosol particles because of solvent evaporation, which is another variable available to optimize drug formulation and device performance for either local delivery or systemic absorption. The stability of drug product in the long term (usually ~2 years) has also to be considered in the device selection process. Some drug compounds can only be packaged in a unit dose because of instability of the drug product in the multidose reservoir; therefore, a device that can be fitted with a unit dose package is needed for such purpose. The drug delivery devices mentioned above have different features and different requirements for the drug formulation, and there is no single delivery device that can meet all the needs for such requirements. To ensure a successful launch of a new inhalation drug product, it is necessary to conduct a comprehensive evaluation of a potential drug candidate for administering via inhalation.

MEDICATION ERRORS

Diane D. Cousins

United States Pharmacopeia, Rockville, Maryland, U.S.A.

INTRODUCTION

A report issued by the Institute of Medicine (1) in November 1999 has drawn unprecedented national attention to the prevalence of medical error, including medication error. The issues and complexities surrounding this problem are compounded by the array of players and solutions that must address it for the public health and safety of the U.S. population. Medical products and their manufacturers are reported not only as part of the problem but also as part of the solution. Ongoing national efforts in medication error reporting and prevention place the pharmaceutical industry far ahead of other medical product manufacturers. These efforts, headed by the *United States Pharmacopeia* (USP), have involved the industry since 1991 by sharing reports received from healthcare practitioners and documenting industry actions to the reported problems. The Institute of Medicine fosters a systems approach to error analysis that focuses on identifying the root cause of error within the system and not on blame of the individual. The report postulates that individuals who commit errors are often well trained, experienced, well intentioned individuals whose misfortune is a result of the unsafe systems in which they operate. With the advent of new technologies and the healthcare-delivery processes surrounding them, new problems are likely to surface, particularly as health systems are redesigned in response to this national call to action. The challenge to the pharmaceutical industry is to learn from its own experiences and the USP national database of errors. The industry will be expected to be knowledgeable of the medication use process for the health setting in which its products are used and to anticipate misuse by designing error out of products.

SCOPE OF THE PROBLEM

Incidence of Medication Errors and Related Morbidity and Mortality

That medication errors occur frequently in U.S. hospitals has been well documented (2–4). In observation studies

carried out between 1962 and 1995 on the rate of administration errors in a variety of inpatient settings, rates ranged from 0 to 59% (5). Estimates that medication errors occur in almost 7% of hospitalized patients have been reported (6). One study found that the frequency of medication errors was 1.4 per admission (4). When approximately 290,000 medication orders were analyzed, Lesar et al. estimated that there were almost two serious errors for every 1000 orders written. Based on a review of death certificates, it was estimated that nearly 8000 people died from medication errors in 1993 compared with almost 3000 people in 1983 (3). Researchers found an error rate at two children's hospitals of 4.7 per 1000 orders (7). Several excellent and comprehensive reviews of the literature on medication errors have recently been published (1, 5).

A variety of error rates for different aspects of the medication use process have been reported. Researchers use different methodologies and definitions of "medication error" and study different aspects of the medication use process (i.e., prescribing, dispensing, and administering). Because there is no national standardization for the denominator used to report medication error rates, the denominator can vary among several: doses dispensed, doses administered, doses ordered, patient days. Therefore, the rates reported in the literature are limited in their use for comparative purposes (5).

Research supports a systems approach to error prevention as well as to investigation of errors (8–11). This means that all aspects of the medication use process, including characteristics of the products themselves, should be explored for ways to improve safety in use.

Cost of Medication Errors

Medication errors are costly to both the patient (direct costs such as additional treatment and increased hospital stay) and to society (indirect costs such as decreased employment, costs of litigation) (1, 5). The cost of medication errors in a 700-bed teaching hospital, based on a study in 11 medical and surgical units in two hospitals over a 6-month period, was estimated at \$2.8 million annually (2). The increased length of stay associated with a medication error was estimated at 4.6 days (2). In a 4-year

study of the costs of adverse drug events (ADEs) in a tertiary care center, 1% of these events were classified as medication errors. The excess hospital costs for ADEs over the study period were almost \$4,500,000, with nearly 4000 days of increased hospital stay (12).

Harm attributable to drugs is a major reason for malpractice claims associated with medical procedures (8). The average compensation for medication errors between 1985 and 1992 was almost \$100,000. Most compensation for medication errors is for larger amounts that are agreed on in out-of-court settlements (5). None of the costs cited above include the cost of patient harm or subsequent hospital admissions (1,3).

USP's EFFORTS TO STANDARDIZE MEDICATION ERRORS

History of USP and Its Involvement in Medication Errors

The USP is a private, not-for-profit organization whose mission is to promote public health through the creation of standards and authoritative information for the use of medicines and related technologies. The USP's authority to set standards is established by the Pure Food and Drug Act and by the Federal Food, Drug and Cosmetic Act. These standards include those for quality, strength, purity, packaging, labeling, and storage of drug products. The USP also creates the official name for drug products and is a member of the United States Adopted Names (USAN) Council that sets the nonproprietary name for drugs in the United States. The USP has been involved in reporting programs for health professionals for nearly 30 years through its USP Practitioners' Reporting Network (USP PRN). These programs support the standards-setting activity by providing practitioner-based experiences about the quality and safe use of medicines in the marketplace.

Nearly a decade ago, the USP agreed to coordinate the medication errors reporting program for the Institute for Safe Medication Practices. The Institute was seeking a home for its grass-roots program and believed the program could have greater impact on the national level. Through the program, the USP hoped to learn of those circumstances in which the product labeling, packaging, or name of product caused or contributed to an error. Then, the USP envisioned setting standards to address the issues and thereby to prevent future errors. In 1994, the USP signed an agreement to purchase the program from the Institute, established the USP Medication Errors Reporting (MER) Program, and began its long-term commitment to

the program as an important part of the USP's standards-setting process. As a condition of the agreement, the ISMP continues to receive copies of reports submitted to this program for its education and advocacy work.

Healthcare professionals report errors in which they are involved as well as errors that they observe or are party to. Reported information forms a database used by the USP to identify problematic situations, to heighten practitioners' awareness of these situations, and to make appropriate interventions regarding issues with drug products.

USP Medication Errors Reporting Program

The prevention of medication errors is the primary objective of the USP MER Program. It collects and analyzes potential and actual medication errors submitted by healthcare practitioners. The program affords healthcare professionals the opportunity to report medication errors and thereby to contribute to improving patient safety by sharing their experiences.

To report an error, practitioners may phone USP toll-free at 1-800-23ERROR. A voice-mail system allows a report to be left 24 hr a day, 7 days a week. Reporters may submit reports anonymously or speak directly to one of USP's health professional staff. Alternatively, a report may be submitted to USP in writing. Report forms (Figs. 1 and 2) may be obtained by calling the USP directly or via an on-demand fax-back system. Practitioners may also access the form online on the USP's website.

Medication error information submitted to the USP is entered into a nationally recognized repository for medication error reporting. This database serves to track, monitor, and analyze medication errors from a systems-based perspective. The USP develops educational resources and materials to disseminate best-practice solutions and error-avoidance strategies to students and practitioners.

The MER Program is presented in cooperation with the Institute for Safe Medication Practices and is a partner in MED WATCH, the FDA's medical products reporting program. Although the FDA does not usually assert jurisdiction over practice issues, which are often involved in medication errors, it is concerned with issues relevant to product quality such as labeling and packaging, and product names, both trade and generic. When medication errors concerning product labeling and packaging are reported through the MER Program, pharmaceutical manufacturers are notified. They respond frequently and voluntarily make changes in labeling and packaging. Depending on the nature of the medication error, the MER Program reports provide material for ongoing discussions between the FDA and manufacturers and, if warranted, for

MEDICATION ERRORS REPORTING PROGRAM

Medication Errors Do Occur

Medication errors can occur anywhere, any time along the drug therapy course, from prescribing through transcribing, dispensing, administering, and monitoring. An error can cause confusion, alarm, and frustration for the health care provider and for the patient. And YES, an error can even cause a death or injury to your patient. The causes of errors are many; for example, lack of product knowledge or training; poor communication; ambiguities in product names, directions for use, medical abbreviations, handwriting, or labeling; job stress; poor procedures or techniques; or patient misuse. Along this continuum, any health care professional may be the cause of or contribute to an actual or potential error.

A Safer Environment for Your Patients

It is important to recognize that health care providers learn from medication errors. By sharing your experience through the nationwide USP Medication Errors Reporting (MER) Program you help your colleagues to gain an understanding of why errors occur and how to prevent them. You can also have a positive impact on the quality of patient care and influence drug standards and information. When others are informed about an error, the chance of recurrence may be lessened. Education regarding medication errors assists health care professionals to avoid errors by recognizing the circumstances and causes of actual and potential errors.

Easy Access

Just call 800-233-7767 to reach a USP health care professional, who will take your report and respond to your concerns. Reports may also be submitted in writing or faxed. All reported information is reviewed by USP for

possible impact on USP standards and information development. Reports are forwarded to the Food and Drug Administration, the ISMP, and when appropriate, the product manufacturer/labeler. If you wish to remain anonymous to any of these sources, the USP will act as your intermediary in all correspondence. While including your identity is optional, it does allow for appropriate follow-up with you to discuss your observations or provide feedback.

USP: A Partner in MEDWATCH

The USP Practitioners' Reporting Network is a partner in MEDWATCH, the FDA's medical products reporting program. As a partner, USP PRN contributes to the FDA's efforts to protect the public health by helping to identify serious adverse events for the agency. This means that your reported information is shared with the FDA on a daily basis, or immediately if necessary.

The USP PRN® is designed to collect experiences and observations from health care providers through three separate reporting programs:

- The USP Drug Product Problem Reporting Program
- The USP Medication Errors Reporting Program
- The USP Veterinary Practitioners' Reporting Program

The Institute for Safe Medication Practices, and the American Veterinary Medical Association cooperate in presenting the USP PRN.

Your Input Could Make the Difference!

regulatory action. Furthermore, reported information identifies broader issues that may become the basis for instituting industry-wide changes. The reported concerns of practitioners have prompted the USP, FDA, and various drug manufacturers to institute numerous changes and improvements to drug products and have contributed to safer medication prescribing and use.

Facility-Based Reporting May Help Define Denominator of Errors

Because of its leadership and experience in the prevention of medication errors, the USP began to receive inquiries from hospitals seeking a nationally standardized database that would help them meet its accreditation requirements and also to compare rates of medication errors among hospitals. Hospitals were willing to share their adverse experiences with other participating hospitals but only if the report could be shared on an anonymous basis. In 1998, the USP developed MedMARxSM, an Internet-accessible database of medication errors for hospitals. Reports submitted to the system are anonymous so that participating hospitals will share information openly. The database is structured to become part of the hospital's internal quality-improvement program and captures not only errors but prevention strategies taken by each hospital in response to errors. This valuable aspect of the national database enables hospitals to practice risk prevention, not just risk management, by learning from the unfortunate experiences of others. It is expected that this database will become a rich repository of information not only for hospitals but for the pharmaceutical industry as well.

USP's First Advisory Panel on Medication Errors

In 1996, the USP created an ad hoc Advisory Panel on Medication Errors. The mission of the Panel was to provide practitioner review of reports received through the USP MER Program and to make recommendations

relative to USP's standards-setting, information, and reporting programs. The Panel chairperson also has a unique opportunity to make broader recommendations through its seat on the National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP). The chairperson of the Advisory Panel on Medication Errors is an ex-officio nonvoting member of the NCC MERP.

The USP Advisory Panel on Medication Errors is a unique and unprecedented opportunity for healthcare professionals to provide peer review of medication errors occurring nationally and to recommend far-reaching strategies for medication error prevention.

The Panel consists of 12 actively practicing volunteers representing medicine, nursing, and pharmacy. This year a Safe Medication Use Expert Committee will be elected to replace the Panel. For the first time, with the formation of this committee, a formal mechanism will be in place in the standards-development process for the purpose of providing direct practitioner input to standards development for the safer use of pharmaceuticals.

A National Coordinating Council Is Initiated

After a few years operating the MER Program, the USP realized that the solutions addressing the myriad issues identified through the program were beyond the mission of its standards-setting capacity. Indeed, errors proved to be multidisciplinary in origin and multifactorial in cause. These other practice-related and process-related aspects surrounding medication errors needed to be addressed. In 1995, the USP spearheaded the formation of the NCC MERP. The NCC MERP promotes the reporting, understanding, and prevention of medication errors relative to professional practice, healthcare products, procedures, and systems (Table 1). The Council is composed of 20 national organizations and agencies, representative of health professions, licensing boards, healthcare facilities, pharmaceutical manufacturers, regulators, standards-setters,

Table 1 The goals of the NCC MERP are far-reaching and encompass the full spectrum of healthcare goals

Goals of NCC MERP
Examine and evaluate the causes of medication errors
Increase awareness of medication errors and methods of prevention throughout the healthcare system
Recommend strategies relative to system modifications, practice standards and guidelines
Stimulate development and use of medication-error reporting and evaluation systems and stimulate reporting to a national system for review, analysis, and development of recommendations to reduce and prevent medication errors

and others (Table 2). The USP is a founding member of and Secretariat to the Council.

Since the Council’s formation, it has produced several important work products. Among them are the standardization definition of the “medication error,” the development of a series of recommendations designed to reduce errors in the medication use process, and the adoption of a severity index for categorizing the outcome of medication errors. The “Recommendations to Correct Error-Prone Aspects of Prescription Writing,” the first set of suggestions issued by the Council, included a list of “Dangerous Abbreviations,” abbreviations that are frequently misunderstood or have often been implicated in medication errors and should never be used (Table 3). In addition to being used in prescription writing, these abbreviations can be found in proprietary product names, on manufacturers’ product labels, and in advertising by pharmaceutical manufacturers. The pharmaceutical industry can support this effort by avoiding the use of these abbreviations. The Council also produced an extensive set of recommendations to reduce errors attributable to labeling and packaging. The recommendations are targeted to regulators and standards-setters, healthcare organizations and professionals, and the industry (Tables 4–7). The practical importance of the Council’s

recommendations lies in a joint endorsement by a diverse group of organizations ranging from experts in safety issues to manufacturers of drug products to regulators. The importance of achieving consensus through a collaborative effort by these national leading healthcare and consumer organizations furthers the adoption of nonpunitive, systems-based approaches to reduce medication errors.

ERROR AVOIDANCE STRATEGIES FOR THE INDUSTRY—DESIGNING ERROR OUT OF PRODUCTS

The USP’s medication error-reporting programs have uncovered a number of reported error-prone situations that could help industry consider the problems that should be addressed in advance, starting with the selection of a drug name and including the development of labeling, packaging, and dosing devices. Some of these cases are presented here. In many, the manufacturer corrected design flaws immediately and successfully. These should be considered showcase examples of industry responsiveness. The cases should also serve to teach certain designs in labels or packaging that should be avoided. And finally, the cases demonstrate how products can be misused because of the systems with which they interface.

Characteristics of Product Errors

Keep in mind that the medication use process is a complex continuum that requires the successful interaction of multiple allied health professionals, technology, and the patient. It can be described as a succession of joined, but distinct processes, known as nodes (Table 8). Each node in the medication use process is, in actuality, a discrete system and presents an opportunity for the occurrence and prevention of medication errors.

Medication errors have been defined in many ways depending on research methodologies, incident reporting systems, risk management, or total quality-improvement systems. The USP uses the broad definition of medication error from the NCC MERP.

A medication error is any preventable event that may cause or lead to inappropriate medication use or patient harm, while the medication is in the control of the healthcare professional, patient, or consumer. Such events may be related to professional practice, healthcare products, procedures, and systems including: prescribing; order communication; product labeling, packaging, and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use.

Table 3 Dangerous abbreviations to never use owing to misunderstanding or misinterpretation

Abbreviation	Intended meaning	Common error
U	Unit	Mistaken as a zero or a four (4) resulting in overdose. Also mistaken for “cc” (cubic centimeters) when poorly written
µg	Microgram	Mistaken for “mg” (milligrams) resulting in overdose
Q.D.	Latin abbreviation for every day	The period after the “Q” has sometimes been mistaken for an “I”, and the drug has been given “QID” (four times daily) rather than daily
Q.O.D.	Latin abbreviation for every other day	Misinterpreted as “QD” (daily) or “QID” (four times daily). If the “O” is poorly written, it looks like a period or a “I”
SC or SQ	Subcutaneous	Mistaken as “SL” (sublingual) when poorly written
T I W	Three times a week	Misinterpreted as “three times a day” or “twice a week”
D/C	Discharge; also discontinue	Patient’s medications have been prematurely discontinued when D/C (intended to mean “discharge”) was misinterpreted as “discontinue,” because it was followed by a list of drugs
HS	Half-strength	Misinterpreted as the Latin abbreviation “HS” (hour of sleep)
Cc	Cubic centimeters	Mistaken as “U” (unit) when poorly written
AU, AS, AD	Latin abbreviations for both ears; left ear; right ear	Misinterpreted as the Latin abbreviation “OU” (both eyes); “OS” (left eye); “OD” (right eye)

Table 4 Recommendations on labeling and packaging to industry manufacturers of pharmaceuticals and devices (adopted May 12, 1997)

<p>The Council recommends that industry not use any printing on the cap and ferrule of injectables except to convey warnings.</p> <p>The Council encourages industry to employ failure mode and effects analysis in its design of devices, and the packaging and labeling of medications and related devices.</p> <p>The Council encourages industry to employ machine-readable coding (e.g., bar coding) in its labeling of drug products. The Council recognizes the importance of standardization of these codes for this use.</p> <p>The Council encourages printing the drug name (brand and generic) and the strength on both sides of injectables, and IV bags, containers, and overwraps. For large volume parenterals and IV piggybacks (minibags), the name of the drug should be readable in both the upright and inverted positions.</p> <p>The Council encourages industry to support the development of continuing education programs focusing on proper preparation and administration of its products.</p> <p>The Council encourages industry to use innovative labeling to aid practitioners in distinguishing between products with very similar names, for example, the use of tall letters such as VinBLAStm and VinCRIStm.</p> <p>The Council encourages industry to avoid printing company logos and company names that are larger than the type size of the drug name.</p> <p>The Council encourages collaboration among industry, regulators, standards-setters, healthcare professionals, and patients to facilitate design of packaging and labeling to help minimize errors.</p>

Table 6 Recommendations to health care professionals to reduce errors due to labeling and packaging of drug products and related devices (adopted March 30, 1998)

The Council encourages healthcare professionals to routinely educate patients and caregivers to enhance understanding and proper use of their medications and related devices. Furthermore, the Council encourages healthcare professionals to regularly participate in error prevention training programs and, when medication errors do occur, to actively participate in the investigation.

In addition, the Council makes the following recommendations to healthcare professionals to reduce errors due to labeling and packaging of drug products and related devices:

1. The Council encourages healthcare professionals to use only properly labeled and stored drug products and to read labels carefully (at least three times—before, during, and after use).
2. The Council encourages collaboration among healthcare professionals, healthcare organizations, patients, industry, standard-setters, and regulators to facilitate design of packaging and labeling to help minimize errors.
3. The Council encourages healthcare professionals to take an active role in reviewing and commenting on proposed regulations and standards that relate to labeling and packaging (i.e., Federal Register and Pharmacopeial Forum).
4. The Council encourages healthcare professionals to report actual and potential medication errors to national (e.g., FDA MedWatch Program and/or the USP Practitioners' Reporting Network), internal, and local reporting programs.
5. The Council encourages healthcare professionals to share error-related experiences, case studies, etc., with their colleagues through newsletters, journals, bulletin boards, and the Internet.

Copyright © 1998–1999 National Coordinating Council for Medication Error Reporting and Prevention. All Rights Reserved.

Table 7 Recommendations to healthcare organizations to reduce errors due to labeling and packaging of drug products and related devices (adopted March 30, 1998)

The Council recommends the establishment of a systems approach to reporting, understanding, and prevention of medication errors in health care organizations. The organization's leaders should foster a culture and systems that include the following key elements:

1. an environment that is conducive to medication error reporting through the FDA MedWatch Program and/or the USP Practitioners' Reporting Network;
2. an environment which focuses on improvement of the medication use process;
3. mechanisms for internal reporting of actual and potential errors including strategies that encourage reporting;
4. systematic approaches within the healthcare organization to identify and evaluate actual and potential causes of errors including Failure Mode and Effects Analysis (FMEA) and root cause analysis;
5. processes for taking appropriate action to prevent future errors through improving both systems and individual performance.

In addition, the Council makes the following recommendations to healthcare organizations to reduce errors due to labeling and packaging of drug products and related devices:

1. The Council recommends that healthcare organizations employ machine readable coding (e.g., bar coding) in the management of the medication use process.
2. The Council recommends reevaluation of existing storage systems for pharmaceuticals by healthcare organizations and establishment of mechanisms to insure appropriate storage and location throughout the organization from bulk delivery to point of use. The following issues should be considered when applicable: storage and location that will help distinguish similar products from one another; storage and location of certain drugs, (e.g., concentrates, paralyzing agents) that have a high risk potential; scope, access, and accountability for floor stock medications; safety and accountability of access to pharmaceuticals in the absence of a pharmacist (e.g., floor stock, eliminate access to pharmacy after hours); labeling and packaging of patient-supplied medications.
3. The Council recommends the development of policies and procedures for repackaging of medications that will clarify labeling to help avoid errors.
4. The Council encourages collaboration among healthcare organizations, healthcare professionals, patients, industry, standard-setters, and regulators to facilitate design of packaging and labeling to help minimize errors.
5. The Council recommends that healthcare organizations develop and implement (or provide access to) education and training programs for healthcare professionals, technical support personnel, patients, and caregivers that address methods for reducing and preventing medication errors.

Dispensing
Administering
Monitoring

Thorough documentation of medication errors provides information about the severity of the error as it relates to the outcome of the patient, the product(s) involved, the level of staff handling the product or processing the order, any contributing factors that may predispose a product to misuse, and the suspected root cause of the error. The USP adds certain codes to MER Program data to characterize the error as it was reported. These codes include the type of error and the possible cause(s) of error. Table 9 lists product characteristics that have been recorded over 9 years to have caused or contributed to a medication error.

The pharmaceutical industry should pay close attention to these items in the earliest stages of product development, including clinical stages. Several years ago the drug zidovudine (an antiviral) was referred to as “AZT” in clinical trials. The abbreviation was brought along as the

product was marketed. However, “AZT” had been a common abbreviation for azathioprine (an immunosuppressant), and several errors were made. The Institute of Medicine report (1) suggests that the FDA develop and enforce standards for the design of drug packaging and labeling that will maximize safe product use. Table 9 should serve as a starting gate of areas to examine.

Case 051133: Poor label design; confusing or incomplete label information; packaging

A pediatric patient was presented to the emergency room (ER) experiencing seizures for which 150 mg of I.V. Cerebyx[®] (fosphenytoin, an anticonvulsant) was ordered. The pharmacy technician took the call for Cerebyx[®] and delivered three 10-ml vials of Cerebyx 50-mg PE (phenytoin sodium equivalents) per milliliter to the ER as a “floor stock” transaction. A nurse then misread the 50 mg PE/ml on the 10-ml container label, making the assumption that the entire vial contained 50 mg PE. The contents of all three vials were prepared for administration. Instead of 150 mg PE, the patient was administered 10 times the intended dose, or 1500 mg of PE. The patient later died. ER staff only discovered the error after the patient’s blood phenytoin levels were returned from the laboratory.

Discussion: Serious medication errors, including some leading to death, have resulted from the interpretation of the Cerebyx[®] product labeling. The terminology

Table 9 Product characteristics from medication errors as reported to USP

Abbreviations—Includes symbols and acronyms used in drug names as well as directions for use.
Dosage form confusion—Confusion due to similarity in color, markings, shape and/or size to another product, or to a different strength of the same product.
Equipment design confusing/inadequate for proper use—Example: administration pump makes it difficult to set precise fluid rate or is confusing to use.
Label (manufacturer’s) design—Physical label design, e.g., contrast of label information and background, letter font, symbol(s), or logo causes information to be overlooked or difficult to read.
Measuring device inaccurate/inappropriate—Scale of graduation markings on medical device (e.g., syringe, dropper) is inaccurate or inappropriate for administering the correct dose.
Names, a brand name/generic name of different products look alike—self-explanatory
Names, a brand name/generic name of different products sound alike—self explanatory
Names, brand names look alike—brand names of different products look alike.
Names, brand names sound alike—brand names of different products sound alike.
Names, generic names look alike—generic names of different products look alike.
Names, generic names sound alike—generic names of different products sound alike.
Nonmetric units of measurement (apothecary)—use of apothecary units of measurement results in misinterpretation (e.g., “cc” (cubic centimeter) written and misinterpreted as “u” (units).
Packaging/container design—the design of the package, bag, syringe, etc., caused or contributed to the error.
Similar packaging/labeling—example: packaging/labeling of two or more different products look similar, causing one product to be mistaken for the other.

on the label, which previously indicated the concentration as being 50 mg of PE per milliliter, was misinterpreted as the total number of PEs per vial. Also, health professionals were reportedly confused by the use of “phenytoin equivalents,” a prodrug concept introduced for this product. As a result, massive fosphenytoin overdoses were mistakenly administered.

Fosphenytoin is a prodrug, a compound that undergoes chemical conversion in the body to become the therapeutically active compound phenytoin. Cerebyx dosage will continue to be expressed in PEs. This terminology was adopted in an effort to simplify therapeutic conversions between phenytoin sodium and fosphenytoin sodium (i.e., 500 mg of phenytoin sodium injection is equal to 500 mg PE of fosphenytoin sodium injection). The manufacturer pointed out that by using PEs, prescribers will not have to make dosing adjustments when converting from phenytoin sodium to Cerebyx or vice versa. To reduce the risk of incorrect dosing, all healthcare providers should prescribe and dispense Cerebyx in PEs.

Parke-Davis has taken action to prevent future errors. The labeling for Cerebyx vials and packaging has been changed to further reinforce the total amount of drug in each vial. This is effective for both the 2- and 10-ml vials of the product. Although the new labeling further clarifies the total quantity of drug contained in the vial, the concentration of Cerebyx will remain 50 mg PE/ml.

Case 51832, 51845: Line extension creates confusion

Muro Pharmaceutical, Inc., introduced a new line extension, Prelone[®] Syrup 5 mg/5 ml (prednisolone, a steroid), to the existing product, Prelone 15 mg/5 ml. Because only one strength of Prelone had been available for many years, it was a general practice for prescribers to write for “Prelone Syrup” without indicating the strength.

Discussion: Manufacturers need to consider the transition time needed by practitioners to become familiar with the existence of a new strength. Confusion of this type is also seen when “long-acting” versions of a product are added to a product line, thereby changing the dosing regime to less frequent intervals. The product name is prescribed without the “long-acting” designation, and a medication error results. In similar cases, suffixes also cause errors when the product line extension adds a second strength and places a suffix such as “XL” after the product name to indicate long-acting release. Prescribers omit the suffix out of habit (for the initial formulation), and the patient receives the shorter-acting medication at the long-acting interval.

Muro Pharmaceutical, Inc., anticipated that a new concentration of an established product could indeed cause confusion and developed new packaging for both

concentrations. Muro also sent mailers that announced the availability of two concentrations of Prelone to 32,000 pediatricians and 65,000 pharmacies, wholesalers, HMOs, and PPOs.

Cases 50446, 50499, 50519, 50534, 50736, 50820, 50918: Poor contrast compromises readability

The unit-dose packaging of the quinolone Levaquin (levofloxacin, an antibacterial) is silver foil with black letters. The dose is reverse shaded. A reporter noted that the packages have to be held at just the right angle to be able to read the label. It was reported to be especially difficult to differentiate between the 250- and 500-mg strengths because the numbers were so difficult to read.

Discussion: Ortho-McNeil is redesigning the packaging for Levaquin to improve readability. Manufacturers should be aware that practitioners often operate in areas that have poor lighting. This makes double-checking the label to prevent errors even more difficult. For some products, there may not be adequate time to read the label carefully the first time without having to look again because of poor contrast. The use of embossed printing on plastic containers has also been reported to be difficult to read because there is no contrast and no paper label to aid in distinguishing the products visually or identifying them properly.

Total volume is the key

Eight reports received from pharmacists expressed concern about the labeling on the Bentlyl[®] (dicyclomine hydrochloride, an antispasmodic) 2-ml ampul. Practitioners reported that the label indicates only the drug concentration, 10 mg/ml, and not the total volume. Some practitioners believe the label information is incomplete. In one report, a 20-mg dose was ordered, but two ampuls were administered (4 ml total instead of 2 ml), leading to an overdose. This happened because the reporter mistook 10 mg as the total contents of one vial.

Discussion: Reports received by Hoechst Marion Roussel have prompted the company to return to the old-style labeling that includes the product's total volume data. According to the firm, this change will be implemented as quickly as possible.

Reports to the USP have identified the need for three items of information to appear on the vial or ampule: 1) the total volume, 2) the strength per milligram and 3) the total strength per total volume.

Although some manufacturers feel it would be unreasonable to include this amount of information on the container (especially containers of 1- and 2-ml sizes),

this information would assure little chance of misinterpreting the contents or strength.

Cases 040925, 050419, 041485: Wholesaler errs due to label similarity

A pharmacist reported that vials of Marsam's cefazolin sodium 1 g and 10 g appear identical in shape and have the same color flip-top closures. The pharmacy ordered the 1-g product from the wholesaler. Instead, the wholesaler sent 10-g bulk vials of cefazolin sodium along with stickers for the 1-g vial. The pharmacy, which does not normally stock the 10-g vials, interspersed the 10-g vials with the 1-g vials in their stock. Several vials were reconstituted in error. Fortunately, no patients received the wrong dose of cefazolin sodium.

In another reported incident, a pharmacist ordered the 10-g vials of cefazolin sodium but received the 1-g vials in error. Intending to reconstitute and then divide the 10-g vials into 1-g doses, a pharmacy technician inadvertently reconstituted the 1-g vials and proceeded to divide the total solution of each vial into ten 100-mg doses. Some of the prepared 100-mg doses of cefazolin sodium were administered to patients instead of their scheduled 1-g doses. No adverse effects to the patients were reported. The pharmacist felt the error occurred, in part, because the vials are identical in size and have similar labels.

Discussion: The pharmacist suggested that the color of the flip-top of the 10-g vial be changed. The company replied that although it is common practice to use color-coded labels and flip-tops to differentiate product lines or strengths, it tries to indicate the individual products in other ways, e.g., by varying the style and format of the label. Marsam revised the labeling of the cefazolin sodium 10-g bulk vial to help distinguish it from the 1-g, single-dose vial. The newly revised labeling included the following:

- the word "BULK" added in two places on the side panel
- screened color added to the box surrounding the product name
- "10 grams" printed in color
- the product name and strength on the back of the label printed in color

The use of color-differentiation is favored, whereas the use of color-coding is controversial because of the limited number of colors, color-blindness in our population, and inappropriate reliance on color in lieu of reading the label.

Case 042031: Packaged measuring devices

An order was written for 30 mg of Cyclosporine (an immunosuppressant) oral solution to be administered to a pediatric patient. However, for several days, the nurse

administered 300 mg, believing that the syringe was calibrated in milligrams, not in milliliters. The oral solution is available as 100 mg/ml. As the pharmacist reviewed the error, he noted that the syringes accompanying the medication were never designed with pediatric patients in mind. It is not possible to calculate any dose less than 50 mg. It is understandable how the nurse assumed that the "3" mark was for 30 mg—it is positioned between "2.5" and "3.5" (which are European expressions for the decimals 2.5 and 3.5). To harmonize products in the global market, the manufacturer chose to follow European convention for expressing numbers, which uses commas and decimals in the reverse manner as that as in the United States.

Discussion: This error is unusual because it involves a global trade issue. Manufacturers would prefer to harmonize products used in the United States with those available in other markets. If dose preparation was centralized in the pharmacy, this error might have been avoided.

Other medication errors involving medication-dispensing devices reported to the USP have included the interchange of devices supplied with specific products. Each device packaged with a medication is calibrated for that medication based on the viscosity and concentration of the specific liquid it delivers. These devices are not calibrated in any standardized way; some are measured in milligrams (mg), others in milliliters (ml), and others in cubic centimeters (cc). Still others have calibrations for the strength per drop or per teaspoonful. Policies should be in place so that the dispensing or use of droppers or calibrated cups provided with specific medications is restricted to those medications. Manufacturers that supply droppers with a stock bottle should supply enough droppers to enable breakdown of the liquid to usable volumes. For example, one company supplied only one dropper with its 8-oz bottle of morphine sulfate, even though the more common quantities dispensed are 2- and 4- oz. Alternatively, manufacturers should package medication in the volume expected to be dispensed per medication order.

Case 52348: Abbreviations

The USP received a medication error report involving the products Neumega® (oprelvekin) and Proleukin® (aldesleukin). Oprelvekin, a recombinant human interleukin-eleven product used to stimulate platelet production in selected patients undergoing chemotherapy, is sometimes abbreviated as IL-11. Aldesleukin, a recombinant human interleukin-two derivative indicated in designated patient populations for the treatment of metastatic renal cell carcinoma, is sometimes abbreviated as IL-2.

In the reported error, a physician used the abbreviation “IL-11” when ordering oprelvekin for a patient. Unfortunately, the order was misinterpreted to be interleukin-two (i.e., the number eleven was perceived to be the Roman numeral two). Five or more healthcare professionals, including pharmacists and nurses, mistook the order to be aldesleukin. The error went undetected for 4 days, until it was noted that the inventory of aldesleukin was nearly depleted.

Discussion: Practitioners should be especially vigilant when orders for these interleukin products are received. If abbreviations have been used in an order, the order should be clarified to ensure that patients receive the intended medication. This medication error exemplifies the value of implementing prescribing guidelines, such as the recommendations adopted by the NCC MERP. Specifically, when writing an order, prescribers should avoid the use of abbreviations, including those for drug names. Drug names should not have accepted abbreviations. Reference materials sometimes refer to these abbreviations as synonyms for the approved drug names. Manufacturers should discourage the use of abbreviations because of the potential to cause medication errors.

The following cases demonstrate how products can be misused because of the systems with which they interface.

Case 052718: Electronic drug reference products

A pharmacist asked one of the clinical pharmacists for information about Cartia®. Because an electronic drug reference listed the active ingredient as aspirin, the pharmacist was prepared to substitute an aspirin product for Cartia. The clinical pharmacist recognized the new product as Cartia XT® (diltiazem, a calcium channel blocker) and prevented the error.

Discussion: The manufacturer of Cartia XT shared the reporter’s concern and contacted the electronic reference source to investigate the matter. The publisher of the electronic reference stated that a salicylate product called “Cartia” is manufactured by Lusofarmaco in Portugal and Smithkline Beecham in Australia. Both Cartia products were verified as active current products by the publisher. The publisher said it has no way of excluding the foreign marketed Cartia because it is an active product imported from a master database that contains many foreign drug products. The electronic reference is published quarterly. “Cartia XT” was entered into the database that is currently being shipped to customers, who will now be able to choose between “Cartia” and “Cartia XT”. This should reduce confusion between the products.

As with many hard copy drug reference books, electronic drug references have lag time between production and the customer’s receipt of the reference databases. Unfortunately, this may result in inaccurate/outdated information and omission of current drug information, causing confusion and misinterpretation of drug information by the users. Healthcare providers should realize that reference sources, including electronic reference databases, are not infallible, and that they are only good as their contents of updated information. As a safeguard, the healthcare providers should make it a practice to check at least two different drug information sources to confirm information.

Case 52125: Computers and processing software

A pharmacist entered an order for Diflucan (an antifungal) for a patient who had been receiving Propulsid (a gastrointestinal emptying adjunct), which is a documented drug interaction. The pharmacy computer system had multiple drug interaction screens. The pharmacist passed these screens by pressing “next screen” without any resistance by the system for this dangerous drug interaction. The patient received two doses of Diflucan. On the second day, the patient coded and later died.

Case 51088

A patient died after 12 mg of I.V. Colchicine (an antidiarrheal medication) was given instead of 2 mg I.V. “until diarrhea,” as ordered. The physician was contacted by the pharmacist but the physician insisted on the dose. The computer program did not warn about the dangerous dose, and nurses had no idea they were giving an overdose.

Case 50908

Amoxicillin was prescribed and dispensed to a patient with a penicillin allergy. The front of the patient’s chart was not marked for an allergy, and the problem list indicating the allergy was covered with a misfiled document. The pharmacy software program does not screen for allergies, and the pharmacy profile was not marked with any allergies.

Digoxin pediatric elixir

Because the computer in one facility was limited to entering doses in milligrams, a neonate patient’s 20 microgram dose of digoxin first had to be converted to the equivalent milligram dose before it could be entered into the computer. A pharmacist incorrectly converted the 20 mcg dose and then entered it into the computer as 0.2 mg (instead of 0.02 mg). Consequently, the patient received four 200 microgram doses of digoxin instead of the 20 microgram

dose as ordered. The patient experienced digoxin toxicity before the error was discovered.

Teaspoonful versus mL

By default, a certain software program printed "teaspoonful" for any syrup preparation when a numerical figure was not followed by a specific measure, such as mL, for the dose. A prescription for $\frac{1}{2}$ mL albuterol syrup every 6 h for a 9-week-old infant was presented to the pharmacy, and the pharmacist entered " $\frac{1}{2}$ " into the computer but did not enter mL. Therefore, by default, the label printed $\frac{1}{2}$ teaspoonful every 6 h if needed for wheezing. The child was administered the overdose and was consequently admitted to the hospital emergency room for observation. Fortunately, the child was released with no permanent damage.

One versus one-half

New computer software was used to enter the directions for a cough medicine with a dose of "1–2 teaspoonsful." Instead, the new software printed the label as $\frac{1}{2}$ teaspoonful. The pharmacist did not check the label against the prescription and dispensed the product with the incorrect directions on the label.

Discussion: Computerized systems have become important tools in today's pharmacy settings. Computers have made prescription processing faster, easier, and more efficient. Computers have also provided for patient information to be readily available. However, as reliance on computers systems grows, care should be taken not to become totally dependent on these systems as the sole check in preventing medication errors.

Similar drug names

Confusion over similarity of drug names, either written or spoken, accounts for approximately one-quarter of all reports to the USP MER Program. Such confusion is compounded by illegible handwriting, incomplete knowledge of drug names, newly available products, similar packaging or labeling, and incorrect selection of a similar name from a computerized product list. The USP has produced a list of more than 1000 drug name pairs that have been reported as confusing. Manufacturers should refer to this list when selecting drug names. Recently, the USP voted to change Amrinone to Inamrinone when it was being confused with Amiodarone and caused fatal errors. This type of change is expensive to the industry and can be avoided by considering the potential for similarity in advance. Technologies and testing protocols, including voice and handwriting recognition, are available to help determine whether a drug name looks or sounds like another.

SUMMARY

The ability to predict error and thus avoid it is the focus of the science of human factors engineering. The adaptation of this science to the medication use process can help to predict the chances that a medication error will occur. Pharmaceutical manufacturers should design products including their names, labeling, and packaging so that errors can be avoided and safer systems and healthcare delivery result.

MATHEMATICAL MODELING OF PHARMACEUTICAL DATA

David W.A. Bourne

University of Oklahoma, Oklahoma City, Oklahoma, U.S.A.

INTRODUCTION

The intent of this article is to give the reader an overview of mathematical modeling as it can be applied to pharmaceutical and especially pharmacokinetic data. The emphasis is on the application of nonlinear regression techniques for the determination of suitable models and best-fit parameter estimates. A number of topics are discussed, including simulation of models described as explicit, implicit, or differential equations; numerical integration methods; optimization algorithms; weighting schemes; evaluation of program output; and approaches for designing future experiments.

The discussion begins with a rationale for modeling and a general approach to the development of suitable models. A brief review of various pharmacokinetic and other pharmaceutical models are followed by a description of methods used to determine calculated values of the dependent variable. The next step in modeling the data involves parameter estimation using a suitable optimization procedure. Not all data points have the same error or uncertainty, thus a weighting scheme should be considered. A variety of schemes are commonly used and all have some advantages. An extremely important part of any modeling exercise is the evaluation of the computer output. Each computer program will provide various information such as plots of the data and residuals, tables of observed, calculated, and residual data, and a variety of statistical parameters. These all can be important in the overall evaluation of the results. The first experiment and the first model are usually not final. Determination of the best model to explain the available data may be required. More experiments may be necessary, thus optimal sampling times or sample sites may need to be explored.

REASONS FOR MODELS

Successful modeling of experimental data should result in a concise and, it is hoped, precise representation of the real world. Successful models allow the exploration of mechanisms, simplify the reporting of experimental results

by the condensation of the data collected allowing useful prediction of future results.

Mechanisms Exploration

Modeling allows the investigator to explore the underlying mechanism controlling various processes. The investigator may develop a hypothesis theoretically or based on preliminary observations. When fully developed, this hypothesis may result in one or more mathematical descriptions. On the basis of this hypothesis, experiments are planned and conducted and the results are analyzed. The most successful hypothesis or mathematical model will best explain the collected data. Variations between the predicted and measured observations may lead to refinement of the hypothesis (or the experimental techniques). An extension of the original experiments may be used to support and confirm the hypothesis. For example, a pharmacokinetic model developed after single-dose administration of a drug may be tested by changing the route of administration or by using multiple-dose administrations.

Data Condensation

Mathematical models allow for considerable data compression. Data that fill many notebooks and/or tables may be summarized by means of the few parameters of a well chosen model. Plasma concentration versus time data collected during a pharmacokinetic study in many patients may be summarized using a volume of distribution term and an elimination half-life. Other models may include more parameters, but there is always a considerable compression in the information required to describe the overall results of the study. An extensive drug stability study involving many samples stored at various elevated temperatures may be summarized as a single time for 10% decomposition at room temperature. Determination of appropriate models can be a very useful method of summarizing an experimental study.

Prediction

A thoroughly tested model with numerically determined parameter values should have very good prediction

potential. A successful drug regimen design relies on the development of suitable pharmacokinetic models. With a good pharmacokinetic model and parameter values determined in similar patients, it becomes possible to calculate successful dosage regimens for future patients, either directly or by using a Bayesian analysis with limited patient data.

GENERAL METHOD

The detailed design of an experimental study varies considerably depending on the area of research, the objectives of the study, the study material available, and available methods of data collection. As many variables as possible should be controlled or measured. Study material and assay methods should be well defined. The sample schedule should be optimized to collect the most informative data. (Optimal sampling strategies are discussed later.) Once the experiment is designed and the data collected, a mathematical model can be used to analyze the results. Typically, a number of models will be evaluated, as will the utility of the data and data schedule. The cycle may include revised analyses and/or revised experiments (Fig. 1). Methods for distinguishing between models and for selecting optimal sampling times are covered later in more detail.

This discussion of mathematical modeling is limited to methods based on the assumption of error in the y (dependent) term only. The objective or minimization function will generally be restricted to the sum of the weighted residuals between the observed and calculated data, weighted sum of squared residuals (WSS). The objective of the mathematical modeling approaches is to adjust the parameter values so that a minimum value of the WSS is achieved.

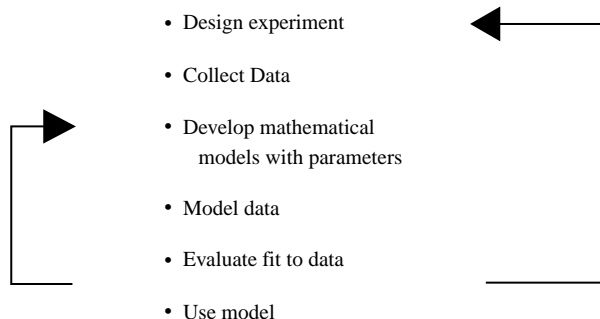

Fig. 1 Mathematical modeling: A general approach.

Error in y Term Alone

With any experiment, measurement or random error may be found in the independent variables, the dependent variables, or both. However, most common modeling programs assume that the independent variable can be set or measured without significant error. Thus, all the error is assumed to be with the dependent variable. Therefore, it is important that the independent variables are carefully measured or controlled. For example, when time is the independent variable, actual times should be recorded and used in the data analyses rather than scheduled times. Although most modeling of pharmaceutical data has confined the error to the y term, there have been attempts to include error in the x value during the fitting process (1).

Least-Squares Criteria

The objective of any modeling exercise is to place a calculated line (based on some relevant mathematical model) as close to the data collected as possible. The difference between individual data points and the calculated line (in a vertical direction—no error in the x terms) is called the residual. The sum of residuals could be zero even with very large residuals for individual points if the negative residuals canceled the positive values. An absolute residual might solve this problem, but more usefully, the squared residual will also achieve the desired result. This is the least-squares criterion. An extension of this is to weight each data point by the inverse of the estimated variance. This term is the objective function, WSS, shown in Equation (1), calculated for “ n ” data points:

$$\text{WSS} = \sum_{i=1}^{i=n} (\text{Calculated Value}_i - \text{Observed Value}_i)^2 \times \text{Weight}_i \quad (1)$$

With normal weighted nonlinear regression, the objective is to minimize this objective function. As it is described later additional terms may be added to the objective function when performing extended least-squares (Eq. 23) or Bayesian analyses (Eq. 24).

Parameter Adjustment

The minimization of the WSS value is achieved by systematic modification of the values of the adjustable parameters of the model chosen. Changing the parameters moves the calculated line and thus the WSS.

Fig. 2 Illustration of the effect of parameter values on WSS value. Calculated using a one-compartment IV bolus model with weighting by $1/\text{Val}^2$.

Achieving the minimum WSS most efficiently is the objective of the minimization algorithms incorporated into the various nonlinear regression programs. Fig. 2 illustrates how the WSS value changes with different parameter values.

MATHEMATICAL MODELS

Most pharmaceutical results can be quantitated and represented by a mathematical model. The model thus developed consists of the dependent variables measured during the experiments (y), independent variables (x), parameters (p ; adjustable or unknown), and constants (c). Thus, a mathematical model may have the general form shown in Eq. 2.

$$y = f(x, p, c) \quad (2)$$

A number of equations will be presented as examples of mathematical models in use in pharmacokinetics and pharmaceutics.

Pharmacokinetics

Pharmacokinetics is the mathematical description of drug absorption and disposition. As such, it lends itself to mathematical modeling and the use of the models developed previously. Within the field of pharmacokinetics,

a different types of models are used. These include compartmental, physiologically-based, and pharmacodynamic models.

Compartmental models: With this type of model, the subject is represented as a number of well mixed compartments. When all the rate processes are first-order, equations in the form of sums of exponential terms are commonly used. Thus a two-compartment model is illustrated by Eq. 3:

$$Cp = A \cdot \exp(-\alpha \cdot t) + B \cdot \exp(-\beta \cdot t) \quad (3)$$

where Cp is the dependent variable (concentration); t is the independent variable (time); and A , B , α , and β are parameters.

With more involved compartmental models, including, for example, Michaelis–Menten elimination kinetics, the model may be described more easily using differential equations. Thus, for a drug eliminated by a first-order excretion process and a Michaelis–Menten metabolic process, Eq. 4 holds:

$$\frac{dCp}{dt} = - \frac{Vm \cdot Cp}{Km + Cp} \quad (4)$$

$$\text{Initial condition} = \frac{\text{Dose}}{V}$$

where dCp/dt is rate of change of drug concentration; Cp is the dependent variable; ke , Vm , Km , and V are parameters; and Dose is a constant. The differential equation is solved numerically to provide Cp values versus time. More information concerning the various equations associated with compartmental pharmacokinetic models can be found in the text by Gibaldi and Perrier (2), Bourne, Triggs, and Eadie (3), Wagner (4, 5).

Physiologically based pharmacokinetic models (PBPK): In contrast to compartmental models where most of the parameters are abstract and empirically based, PBPK models include many physiologically relevant parameters. These parameters include tissue or organ volumes, blood or plasma flow rates, and partition coefficients between blood and tissue. In some studies, protein binding or tissue binding parameters may be included. Drug elimination is commonly expressed as renal, hepatic, or other clearance. These models are expressed as mass balance-based differential equations. Thus, the rate of change of drug concentration in any organ or tissue of interest is given by Eq. 5:

$$V \cdot \frac{dC}{dt} = [\text{Mass of drug flowing in} - \text{Mass of drug flowing out}] \quad (5)$$

For a single noneliminating organ, this becomes Eq. 6:

$$V \cdot \frac{dC_p}{dt} = \left[Q_i \cdot C_b - \frac{Q_i \cdot C_i}{R_i} \right] \quad (6)$$

where C_i and C_b (drug concentration in tissue “ i ” and blood) are the dependent variables; t is the independent variable (time); and Q_i , R_i , and V_i are tissue blood flow rate, tissue to blood partition coefficient, and tissue volume, respectively. More detailed descriptions of these types of models can be found in the text by Gibaldi and Perrier (2) or in the papers of Bischoff and Dedrick (4, 6).

Pharmacodynamic models: These models are designed to relate drug effect (dependent variable) to drug concentration or time (independent variable). Included in these models may be disposition parameters, such as volumes and rate constants, as well as drug effect parameters such E_{\max} (maximum effect) and $EC_{50\%}$ (concentration eliciting 50% of maximum effect). The Hill equation has been used successfully to describe the relationship between effect and drug concentration. More information about these types of models may be found in the text by Gibaldi and Perrier (2) or the paper by Sheiner et al (7). Jusko proposed an alternative model involving equilibrium with the hypothetical receptor site (8). Recently, Jusko et al. have described four basic models to describe indirect drug effects that include tolerance or rebound, which should be useful (9, 10).

Stability

Drug stability studies may require the use of zero-, first-, or second-order reaction models. Reaction rates may be measured as a function of pH and buffer concentrations to determine the influence of various catalysis possibilities. For example, the hydrolysis of a compound may be pseudo first-order, as shown in Eq. 7:

$$\frac{dC}{dt} = -k' \cdot [C] \quad (7)$$

where the first-order rate constant, k' , can be expressed as in Eq. 8:

$$k' = k_0 + k_H \cdot [H^+] + k_{OH} \cdot [OH^-] + k_{HB} \cdot [HB] + k_B \cdot [B^-] \quad (8)$$

Here the terms, k_0 , k_H , k_{OH} , k_{HB} , and k_B , refer to noncatalyzed and specific acid, specific base, buffer (acid), and buffer (base) catalysis. Additional details regarding the models required to describe drug stability studies can be found in textbooks such as the one by Carstensen (11).

SIMULATION OF DATA

Mathematical models involve many different types of equations. These may be explicit, implicit, or differential equations. Dependent variables expressed as explicit equations are easily calculated. For example, plasma concentrations after a single oral dose can be calculated as in Eq. 9:

$$C_p = \frac{F \cdot \text{Dose} \cdot ka}{V \cdot (ka - kel)} \cdot \{ \exp(-kel \cdot t) - \exp(-ka \cdot t) \} \quad (9)$$

Implicit equations include the dependent term in a form not readily separated from the other terms in the equation. One example in Equation (10) for drug concentrations after IV bolus administration, following Michaelis–Menten elimination kinetics as described by Wagner (12):

$$C_0 - C + K_m \cdot \ln\left(\frac{C_0}{C}\right) = V_m \cdot t \quad (10)$$

Here the dependent variable C is found in two parts of the equation and cannot be solved directly. Thus, an iterative method (13) may be necessary to determine the value of C at each value of t , the independent variable.

Integration Methods

Many processes in the pharmaceutical sciences are dynamic. Thus, models of these processes may commonly involve differential equations, which must be numerically integrated at each step in the optimization procedure. A variety of numerical integration methods can be used, and some of these are discussed later.

When a model is expressed as differential equations, they usually must be integrated before the optimization can be performed. Thus, the differential terms must be converted into values for the dependent variable. For example, the differential Eq. 11:

$$\frac{dC_p}{dt} = -kel \cdot C_p \quad (11)$$

could be converted into the integrated Eq. 12:

$$C_p = \frac{\text{Dose}}{V} \cdot \exp(-kel \cdot t) \quad (12)$$

Conversion from the differential equation form can be performed by analytical methods or numerically, using appropriate computer algorithms. Analytical integration may be mathematically intensive (or impossible), and numerical integration tends to be computationally intensive. Selection of the best approach depends on the equations involved.

Laplace transforms

Integration of differential equations can be quite involved and the subject of complete college courses (14). However, one useful technique is the method of Laplace transforms. An excellent tutorial is presented in the two papers by Mayersohn and Gibaldi (15, 16). Benet and Turi (17), and Benet (18) present more advanced techniques, such as the input and output disposition functions and the "fingerprint" technique for the solution of differential equations.

Another approach presented by Yamaoka et al. (19), uses a fast inverse Laplace transform to generate the integrated equation data. Thus the model is described in terms of the Laplace transform equations and solved numerically.

Numerical integration

Numerical integration also starts with a number of differential equations and initial conditions. However, now the computer program performs the integration. Using carefully defined algorithms, the computer program is able to start with the initial condition(s) and project forward with increasing values of the independent variable (often time) according to the slope given by the differential equation(s). With a careful selection of algorithm, accurate approximations to the required result can be calculated efficiently. The general approach can be understood more easily by looking at a simple point-slope method such as Euler's method. However, these methods are not

necessarily the most efficient. Runge–Kutta methods, including the Fehlberg modification, have advantages with the usual differential equations encountered in pharmacokinetics and pharmaceuticals. For systems where the rate constants are widely disparate, so-called "stiff" systems, other methods become more useful.

Point-slope methods: Euler's method follows directly from the initial condition as a starting point and the differential equation as the slope (Fig. 3). Consider the simple model of a single differential Eq. 13 with one first-order rate process:

$$\frac{dC_p}{dt} = -k_{el} \cdot C_p \quad (13)$$

with an initial condition of C_p at time = 0 of C_p^0 . Thus, the change in the value of C_p from time = 0 to time = Δt is shown by Eq. 14:

$$\Delta C_p = \frac{dC_p}{dt} \cdot \Delta t \quad (14)$$

and the value of C_p at time Δt by Eq. 15:

$$C_p^{\Delta t} = C_p^0 - k_{el} \cdot C_p \cdot \Delta t \quad (15)$$

If Δt is sufficiently small, relatively accurate calculations can be performed. Unfortunately, very small step sizes are often required for reasonable accuracy and truncation errors then can be significant. Thus, this method is not generally used with nonlinear regression programs.

Euler's methods can be derived from a more general Taylor's algorithm approach to numerical integration. Assuming a first-order differential equation with an initial value such as $[dy/dx] = y' = \text{function of } x$, and $y = f(x, y)$ with $y(x_0) = y_0$, if the $f(x, y)$ can be differentiated with respect to x and y , then the value of y at $x = (x_0 + h)$ can be found from the Taylor series expansion about the point $x = x_0$ with the help of Eq. 16:

$$y(x) = y_0 + hy'(x_0) + \frac{h^2}{2!} \cdot y''(x_0) + \dots \quad (16)$$

where h is an increment in x , that is Δt . It can be seen that including only the first two terms on the right side of Eq. 16 leads directly to Euler's method. This method gives increased accuracy with more terms on the right side of the equation. However, it is not readily applicable as a general-purpose procedure because of the requirement for higher-order derivatives. It has been useful theoretically in the development of more general-purpose methods such as the Runge–Kutta methods.

Runge–Kutta methods: The Runge–Kutta methods attempt to improve the accuracy of the calculation and avoid the evaluation of higher-order derivatives. The

Fig. 3 Illustration of the point-slope method.

general approach is to determine values of the first-order differential equation at subintervals of the chosen step size. The way in which these subinterval results are combined can be derived from the Taylor series expansion. The most common of these Runge–Kutta methods is the classical fourth-order version. The values of the function are calculated four times for each step to improve the accuracy of the calculation. For complex functions, this may be a disadvantage. Another problem with this method is that it lacks any automatic step-size control. Additional details of these Runge–Kutta methods may be found in textbooks on numerical analysis (13).

The Runge–Kutta–Fehlberg is a further modification of the Runge–Kutta fourth-order method. It uses a fifth function evaluation to determine the appropriate step size. This method appears to be very efficient for nonstiff systems of differential equations. Additional details regarding this method and a computer listing can be found in a report by Fehlberg (20) and in the chapter by Watt and Shampine (21).

Multistep methods: Another class of methods, called multistep methods, involves the use of more than one previous value in the calculation of the “next” value. With the slope-point and Runge–Kutta methods, a single starting point (and the differential equation) is all that is required for the calculation of the next value at $(x + h)$. With a commonly used four-step method, values at $(x-3h)$, $(x-2h)$, $(x-h)$, and x are required in the calculation of y at $(x + h)$. One such method is that of Adams and Bashford (22).

The advantage of these techniques is that they require only one (additional) function evaluation for each step compared with four or five evaluations for the typical Runge–Kutta method. Thus, they should be faster. Their principle disadvantage is that they are not self-starting. Another method, Euler’s or Runge–Kutta, is required to calculate the first (three) values at x , $(x + h)$, and $(x + 2h)$ before the Adams–Bashford multistep equation can be used to continue the calculation. Additional starting values are also required whenever the step size is changed.

An extension of the multistep methods is the predictor-corrector approach. Here, the Adams–Bashford equation may be used to calculate a “predicted” value for y at $(x + h)$. Then a second, corrector, equation is used to refine the value of y . If the difference between the predictor and corrector values is within specified error limits, the calculation is continued to the next step, otherwise the step size will be adjusted to maintain the error limits specified. With fewer function evaluations per step, these methods can be faster than the Runge–Kutta methods; however, they are not self-starting.

Methods for stiff equations: Stiff systems of differential equations occur commonly with physiologically based models. That is, very fast processes and very slow processes occur in the same model. The ratio between the fastest and the slowest rate constant can be used as an index of stiffness. With ratios greater than 500, a number of the “nonstiff” numerical integration methods become very inefficient. Gear’s method for solving stiff systems has achieved wide acceptance (23, 24) and has been incorporated into a number of nonlinear regression programs such as SAAM II and Boomer. Adam and Gear’s methods are both included in Gear’s DIFSUB algorithm. The user has to specify which method they wish to use. The differential equation solver LSODA included in the ADAPT II program automatically switches between Adam and Gear’s methods as required.

FITTING MODELS TO DATA

Fitting the model to the observed data is an important task. Each mathematical model studied consists of independent and dependent variables, constants (possibly), and parameters that have to be estimated. The objective is to reduce the overall difference between the observed data and the calculated points by adjusting the values of the parameters. As mentioned earlier, the methods to be discussed assume that there is no error in the independent variable. Also, in general, the criteria of “best” fit will be the weighted sum of squared residuals between the observed and calculated data, the WSS. The chosen model can be validated in part by accurately describing the observed data.

Graphical Methods

It is often possible to manipulate the mathematical model into the form of a straight-line equation. For example, the one compartment pharmacokinetic model after an IV bolus can be expressed as a differential equation or as an exponential equation as shown earlier. By taking the natural log of the exponential equation, Eq. 17 in the form of a straight line can be derived:

$$\ln(Cp) = \ln(Cp^0) - kel \cdot t \quad (17)$$

Thus, by graphing the data on semilog graph paper and drawing a straight line through the data it is possible to read Cp^0 from the intercept and calculate kel from the natural log slope, as in Eq. 18:

$$kel = -\text{slope} = \frac{\ln(Cp^1) - \ln(Cp^2)}{t_2 - t_1} \quad (18)$$

Graphical methods have a number of advantages. They are usually fast and, when performed carefully, can give accurate results. A major plus for the method is the ability to “see” the data and visually determine whether there are systematic deviations from the chosen mathematical model. Graphical evaluation of the data may lead to consideration of alternative models. Graphical methods can be very useful in the estimation of initial parameter values. Unfortunately, these methods are not universally available, because it may not be possible to produce a straight-line equation. When manipulating the model to produce a straight line, the observed data is often “transformed,” which may involve taking the logarithm or the reciprocal of the observed data. With other models, more involved transforms are required. This not only distorts the data but also the error or variance of the data. When using linear regression by the graphical approach, it is assumed that the error in each x -value is similar. Once the data are transformed, this may not be true. Another problem that is especially relevant with the use of log transforms and semilog graphical data representation involves the visual distortion that can occur. Typically, much of the graph is taken up by the least accurate data points; i. e., the last few data points at the lowest (and thus, the least well defined) concentrations may dominate the graph. Thus, although graphical techniques such as semilog data plots may be useful in the determination of initial estimates, they are not as suitable for complete data analysis or presentation of the final results.

Other approaches have been used for more complex models. These include curve stripping or the method of residuals (2), either manually or using a computer program

such as CSTRIP and ESTRIP (25, 26). These techniques can separate a multiexponential curve into its component parts for initial estimates. Other techniques include deconvolution methods specific to the one and two compartment pharmacokinetic models (27, 28). The objective of the deconvolution method is to mathematically “subtract” the results obtained after IV administration from the oral or extravascular data. This results in information about the input or absorption process alone. More general methods have been presented by various researchers that do not rely on a particular compartmental model (29–31).

Nonlinear Regression Analysis

For all mathematical models that are not “naturally” straight lines, nonlinear regression analysis is often the best approach. The observed data and the corresponding dependent variable can be analyzed without transformation. Thus, the data and the error or variance are not distorted during the analysis. If necessary, clearly defined weighting schemes can be applied. Furthermore, multiple observation sets can be readily accommodated.

Nonlinear regression analyses involve relatively complex calculations and thus are well suited to computer assistance. However, the program must have a well developed sequence of steps or algorithm to follow. Some methods are better than others. The program is asked to find the minimum point on a weighted sum of squares (objective or minimized function) surface. For two parameters, this can be represented as a three-dimensional surface (Fig. 4).

With more parameters, it is difficult to represent the shape of the WSS surface, but the program still moves to a minimum value of the WSS. Depending on the shape of this surface, there may be a number of local minima. That is, regions that are “lower” than the surrounding surface but *not* the “global” minimum. The objective of the nonlinear regression analysis is to reach the global minimum. Helpful strategies include: 1) careful calculation of initial estimates; 2) repeated analyses with different sets of initial estimates; and 3) careful evaluation of the program output, especially the plot of calculated and observed data versus time (x -value).

Many basic algorithms, each with a number of refinements, are useful in the search for a global minimum. Some of these methods are described briefly. These are the grid search, steepest descent, Gauss–Newton, Marquardt, and simplex methods.

Grid search

This method is more informative, but it can be quite slow. Its major objective is to produce a weighted sum

Fig. 4 A three-dimensional surface plot of WSS versus elimination rate constant and volume of distribution for a two-parameter model.

of squares surface diagram. In addition the minimum calculated WSS is estimated. The three-dimensional plot in Fig. 4 was calculated by this method. The calculation is set up by inputting the upper and lower limits of each parameter of interest. This range is split into a number of steps, and the program calculates the WSS at each point on the grid. The more steps, the smoother the surface but the longer the calculation. A three-parameter problem with only 10 steps per parameter (a relatively coarse grid) requires 1000 ($= 10 \times 10 \times 10$) calculations of the WSS. With many parameters and steps, these calculations can be very lengthy. This method is not usually used for nonlinear regression analyses, but its output may be educational.

Steepest descent

If the WSS surface is seen as similar to a geographical section with hills and valleys (at least for the two-parameter surface), the steepest-descent method would appear to follow the path of a round ball moving towards the minimum. When translated to a computer algorithm, some of the disadvantages become more apparent. The basic approach is to calculate the slope of the surface at the point of the initial (or current) parameter values. This can be calculated as $dWSS/dP$ over some small increment for each of the parameters P . By combining each of these partial derivatives over all the parameters, the direction of movement towards the minimum can be calculated. The second part of the problem is the distance h to move in the specified direction. This must be determined by finding the minimum WSS in the direction calculated from the slope. This means extra calculations of the WSS, which makes this process less efficient, especially as it approaches the minimum. The new parameter value is calculated with the help of Eq. 19:

$$P_{\text{new}} = P_{\text{old}} - h \bullet \frac{dWSS}{dP} \quad (19)$$

This new value is used as the P_{old} for the next iteration.

Gauss-Newton

If we can assume that the WSS surface between the initial estimate and the global minimum is convex, a Taylor series expansion leads to the Gauss–Newton approximation for a step closer to the minimum (32). Thus, the next point on the surface can be calculated as in Eq. 20:

$$P_{\text{new}} = P_{\text{old}} - \frac{dWSS}{dP} \bigg/ \frac{d^2WSS}{dP^2} \quad (20)$$

This method gives both a direction and a distance. Close to the global minimum, where the surface is

typically more regular, the convergence can be dramatic. Farther from the minimum, the surface may not be convex or as smooth, and the method may become slow or even move away from the minimum. Thus, good initial estimates are very helpful.

The Gauss–Newton method can be improved by using two modifications. The first is a damping process. Thus, the new WSS is calculated with the help of P_{new} calculated using Eq. 20. If this WSS is worse than the original WSS, the step size is halved, and the WSS is calculated again. This is repeated until a preset number of halvings (dampings) occur or a better WSS is achieved. Excessive damping can occur close to the minimum if the WSS surface is very flat, owing to numerical instability. In this case, the uncertainty in the final parameter values (expressed as coefficients of variation or confidence intervals) may be large.

A second method of improving the Gauss–Newton method is the Marquardt modification (33). In this case, the equation for P_{new} is modified by the addition of another term, μI , as in Eq. 21:

$$P_{\text{new}} = P_{\text{old}} - \frac{dWSS}{dP} \bigg/ \left(\frac{d^2WSS}{dP^2} + \mu I \right) \quad (21)$$

The analysis is started with a large value of μ , which has the effect of moving the equation in the direction of the steepest-descent method, which is better farther from the minimum. As the calculation approaches the minimum, μ is reduced progressively to automatically approach the Gauss–Newton method, which is better near the minimum.

Simplex

Another approach that is different from the previous methods is the simplex method of minimization (34). It involves the formation of a simplex, a geometric shape with $(m + 1)$ sides, where m is the number of parameters on the WSS surface. The WSS is calculated at each corner of the simplex and compared. The movement of the simplex across the WSS surface (toward the minimum) is controlled by a small number of rules. For example, the point with the highest WSS is reflected across the centroid (center of the simplex) to produce a new point. If this point has the lowest WSS, it is extended again. A point with a larger WSS causes the simplex to contract. By a series of such steps, the simplex moves across the WSS surface to approach the minimum value. Although the simplex method can be relatively slow, it has the advantage of computational simplicity that makes it useful for a variety of nonlinear regression problems.

Weighting Schemes

After selecting and describing an appropriate model, choosing a numerical integration method (if necessary) and a fitting algorithm, the mathematical modeler may need to select a weighting scheme for the data to be analyzed. Ideally, each data point is independent and has normally distributed error. Even when this is true, the magnitude of the variance or error in each data point may not be equal. Thus, a weight equal to the reciprocal of the variance may be applied to each data point in the calculation of the overall WSS. Information about the variance, standard deviation (SD), or coefficient of variation (CV) for each data point or how these values vary over the complete data set to be analyzed can be very useful in the selection of a “best” weighting scheme. The weighting scheme is best evaluated by looking at the weighted residual plots as described later.

If a single data set is to be analyzed (at one time) and the variance is similar for each data point, an unweighted regression may be appropriate; i.e., each data point may be given an equal weight. Unweighted regression may be appropriate when the variance is small. With physical systems, the weighting scheme may become less important. The weighting scheme becomes much more important when there is significant error or uncertainty in the data. With biological studies, such as pharmacokinetic determinations, the error in the measured data may be considerable, and the choice of weighting scheme becomes more important.

When the values of the dependent variable have considerable error and cover a relatively large range of values, a carefully selected weighting scheme may be useful or necessary. When the CV about a series of data points is constant, that is, there may be $\pm 5\%$ error in each data point, a weighting scheme can be estimated. Because the CV is equal to $SD/Value$:

$$SD = \text{Observed value} \times CV \text{ and Variance}$$

$$= \text{Observed value}^2 \times CV^2$$

With a single data set, the CV^2 can be ignored. However, when fitting more than one data set simultaneously, this value is important. Thus, the weight would be proportional to $1/\text{observed value}^2$. Other weighting schemes include a more general expression, with a and b as constants (35):

$$\text{Variance} = a \times \text{Observed value}^b$$

Provision may be made for an assay sensitivity term:

$$\text{Variance} = a + b \times \text{Observed value}^c$$

Another possibility, especially useful in a clinical setting with older concentration-versus-time data, is to apply a smaller weight to older data (36):

$$\text{Variance} = a + b \times \text{Observed value}^c \times d^{(\text{last} - \text{time})}$$

with d typically equal to 1.01 to 1.05.

Careful consideration of the data may suggest a number of equations for the estimated variance of the error in the data. The analyst should consider the overall results produced by the chosen weighting scheme and especially confirm that the weighted residual plots are satisfactory.

Selection of appropriate weighting schemes is even more important if the analyst is modeling more than one data set simultaneously. For example, drug concentration in plasma and cumulative amounts of drug eliminated into urine may have been collected. Consequently, plasma concentrations may range from 0 to 25 $\mu\text{g/ml}$ and will have quite different variance values to cumulative amount of drug in urine data ranging from 0 to 250 mg. If an unweighted analysis was undertaken, the plasma data (numerically lower values for concentrations) would tend to be ignored. Alternately, if the amount of drug excreted into urine was expressed in grams, not in milligrams, these data would be ignored during the fit because they are now much smaller numerically than the plasma concentration. Obviously, an appropriate weighting scheme must be developed. The same problem may occur if plasma concentrations after intravenous and oral administration is to be analyzed together. Again, consideration of the computer program output, especially the weighted residual plots, can help to confirm a chosen weighting scheme.

Iteratively Reweighted Least Squares

The variance formulas used in ordinary weighted least-squares analysis use the observed data values. This is easier to calculate because the observed values do not change during the fitting process. However, there can be advantages to using the calculated data values, instead of the observed values, in the variance formulas. For example, very low data points (which may have considerable error) are not given disproportionate weight. Thus, the technique of iteratively reweighted least squares may be useful (37).

Extended Least Squares

Another approach to weighting the data uses the data itself to develop the variance equation. This is the extended least squares (ELS) method (37, 38). Parameters for the variance equations are included in the fitting process as

well as parameters for the chosen model. Thus, extra data points are necessary for a successful analysis. Furthermore, the analyst must decide the form of the variance equation. An example of a typical variance equation is:

$$\text{Variance} = a \times \text{Calculated value}^b$$

where a and b are parameters to be fitted to the data. The objective function must also be altered with the ELS method because driving the calculated variance to a very large value would automatically make the WSS very small, regardless of the fit to the data. Thus, a $\ln(\text{variance})$ term is added to the WSS formula as a penalty, and the objective function to be minimized becomes Equation (22):

$$\text{Objective function} = \sum_{i=1}^{i=n} \frac{(C(\text{obs})_i - C(\text{calc})_i)^2}{\text{variance}(P, PV, t_i)} + \ln(\text{variance}(P, PV, t_i)) \quad (22)$$

where P values are the parameters of the model, PV values are the parameters of the variance equation, and n is the number of data points. This method is available in the nonlinear regression programs ADAPT II and NONMEM.

Bayesian Analysis

The analysis of clinical pharmacokinetic data offers additional challenges. Typically, the number of samples available from an individual patient can be limited. In some cases, only one or two samples may be available. If population-based pharmacokinetic values are available, it may still be possible to analyze this limited clinical information using a Bayesian approach (36). Using patient and population information, the objective function becomes a function of both the residual between the observed and calculated data (as in weighted least squares) and the residual between the population and the calculated values of the parameters, as shown in Eq. 23:

$$\text{Objective function} = \sum_{i=1}^{i=n} \frac{(C(\text{obs}) - C(\text{calc})_i)^2}{\text{Variance for data point}} + \sum_{j=1}^{j=m} \frac{(P(\text{pop})_j - P(\text{calc}))^2}{\text{Variance for parameter}_j} \quad (23)$$

Analysis of Population Data

A typical pharmacokinetic analysis of data from a single individual results in estimates for the values and variance (or SD) of each parameter. The calculated variance gives

an estimate of the closeness of fit, the adequacy of the number of data points, and the error in the data values. If this analysis is repeated in a number of individuals, it is also possible to obtain some information about the average population value and intersubject variance. With sufficient data available from each subject, this two-step approach can be efficient using any number of nonlinear regression programs.

A few programs are now available that allow the efficient simultaneous data analysis from a population of subjects. This approach has the significant advantage that the number of data points per subject can be small. However, using data from many subjects, it is possible to complete the analyses and obtain both between- and within-subject variance information. These programs include NONMEM and WinNONMIX for parametric (model dependent) analyses and NPEM when nonparametric (model independent) analyses (39) are required. This approach nicely complements the Bayesian approach. Once the population values for the pharmacokinetic parameters are obtained, it is possible to use the Bayesian estimation approach to obtain estimates of the individual patient's pharmacokinetics and optimize their drug therapy.

Evaluation of computer program output

Once the computer program completes the calculations, it is time to evaluate the output, which should be scrutinized very carefully. Each line is there for a reason. Obvious errors of data entry can be found by looking at the data tables and plots. Model misspecification may be more difficult to access. Each computer program will present users with an array of information. During the evaluation of this output, the fit to the data, the weighting scheme used, and parameter values can be assessed. Each of the items that may be output by a nonlinear regression program should be considered.

Observed and calculated data

The table of observed and calculated data includes the observed x and y values. Some programs are sensitive about how the data should be entered, and data entry errors may be common. This table should be checked to ensure that the program is working with the correct numbers. The calculated data can be compared with the observed data. If the numbers are not similar, there may be problems with parameter value limits or model specification. A residual or weighted residual is often included. These values should be of similar magnitude and randomly positive and negative. The most important use of this table is to ensure correct entry of the observed data.

Most programs provide plots of observed and calculated data versus the independent variable x . On both linear or semilog axes, these should be similar, with the calculated line running close to the observed data. If the observed and calculated data appear to be going in different directions, incorrect model specification should be suspected. If the two lines have a similar shape but do not coincide, may be a parameter value limit is causing a problem. Alternately, the program may have fallen into a local minimum. Rerunning the analysis with better (different) initial estimates may help. This plot can be useful in the identification of incorrectly entered data or outliers.

Another plot often presented is a plot of calculated data versus observed data (with a line representing identity). This can be a sensitive plot for the assessment of the model chosen. Significant systematic deviations from the identity line may indicate the need for additional parameters in the model.

Final Parameter Values

Most programs present the final “best-fit” values of the parameters with some indication of the uncertainty in these values. Parameter values far from the expected results may indicate an incorrectly specified model. Possibly a model constraint has been incorrectly specified. Incorrect units may be causing a problem. The uncertainty in the values may be expressed as an SD or CV. Alternately a CI may be calculated. A high CV, higher than 20% and especially higher than 50%, generally indicates a parameter that is not well described by the data. Maybe the model has too many parameters. High CV values may be caused by small number of data points or data with larger error. Samples may need to be taken from additional parts of the model to fully specify the parameters of interest. This becomes a problem of identifiability, as described below. Many programs also provide a correlation matrix of the estimated parameters. A high correlation (>0.95) may suggest that the model has too many parameters and that a simpler model may be satisfactory.

Weighted Residual Plots

The weighted residual plots can be very useful in the evaluation of the chosen model and weighting scheme. The basic approach is to look for a pattern in the plot. Two types of patterns may be evidence of a problem in the analysis. Residuals larger on one side of the plot compared with the other may indicate a problem with the weighting

scheme. A trend in the residuals either sloping up or down, or a “U” or inverted “U” shape, would suggest that one or two additional parameters should be added the model as seen in Fig. 5. The best result is a plot with no discernible pattern. This would support both the model and the weighting scheme selected for the analysis. A more complete discussion of residual plots can be found in the text by Draper and Smith (40).

Statistical Output

The WSS or other objective function is the major statistical parameter provided by any of the nonlinear regression programs. Typically, the analyst is looking for a minimum WSS value. However, this can be misleading if a variety of weighting schemes has been used throughout the analysis phase. For example, with observations greater than 1, the WSS when using an equal weight scheme will be much larger than with a reciprocal observed value or observed value-squared weighting scheme. Thus, comparisons of WSS (or WSS-related functions) must be made between analyses using identical weighting schemes. Some programs will normalize the sum of the weights to be equal to the number of data points. This may help in the comparison of results across the weighting scheme, but all

Fig. 5 Plot of weighted residual versus time after fitting data generated with a two-compartment model using a one-compartment model.

comparisons should be made with the same weighting scheme. Comparison of WSS values between similar data sets may help in the identification of sampling or analysis problems.

The correlation coefficient R and the coefficient of determination R^2 are often provided. Both terms are meant to indicate closeness of fit, with a value of 1 representing a perfect fit. With many data sets, a high value of R (greater than 0.9) seems relatively common even with a fit that visually looks poor. Thus, the analyst should not put too much emphasis on this parameter. Similarly, high values of R^2 are relatively easy to achieve. Although these parameters are widely used with unweighted linear least squares, they do not appear as useful in weighted nonlinear regression.

Comparison Between Different Models

A number of the output items already described are useful in the selection of a “best” model. Systematic deviations in the observed and calculated data plots may suggest the need for a model with additional parameters. Large values for the parameter CV values (or wide confidence intervals) may indicate a model with too many parameters. A number of patterns in the weighted residual plots may suggest the addition of parameters to the chosen model. The guiding rule is to start with the simplest model consistent with the data (and theory). As more parameters are added, it is expected that the WSS will decrease. The question becomes, has the inclusion of additional parameters produced a significant decrease in the WSS. Although developed for unweighted analyses, a number of approaches to this question have been used with weighted nonlinear regression. As suggested by Mandel (41) and Boxenbaum et al.(42), an F value can be calculated after the analysis using two different models (with different numbers of parameters), as shown by Eq. 24:

$$F(df_j - df_k, df_k) = \frac{WSS_j - WSS_k}{WSS_k} \times \frac{df_k}{df_j - df_k} \quad (24)$$

If the calculated F value is higher than the tabled F at the chosen level of significance (often 0.05), the use of the more detailed model is supported. Another commonly used parameter is the Akaike’s Information Criterion (AIC) value (43, 44). It is calculated for each model, and the model producing the lowest value (most negative value) is considered the better model. The AIC value is calculated using the number of data (n), WSS, and the number of parameters (m), as in Eq. 25:

$$AIC = n \ln(WSS) + 2 \times m \quad (25)$$

A variety of other criteria have been developed that may also be useful. It is hoped that each criterion (parameter variability, graphical output, AIC, F test, etc.) will complement each other, allowing the analyst to make an objective decision.

THE DESIGN OF FUTURE EXPERIMENTS

Once the first modeling phase is complete, the analyst may wish to consider revision of the experimental design to test the chosen model or to determine more reliable values for the parameters of the model. This leads to a number of approaches.

Extend the Range of the Current Model

Typically, a series of experiments is performed within a fixed framework. From these results, a “best” model may be selected and parameters determined. One test of this model is to make predictions beyond the range of the original experiments. These predictions can be tested by performing more experiments in the region of the new predictions and determine how well the model simulates the data. For example, a single-dose study may be conducted with data collected and analyzed to give a two-compartment pharmacokinetic model as most appropriate. This model could be tested by predicting and measuring drug concentrations after multiple-dose administration. Alternately a different route of administration may be used.

Identifiability and the Determination of Appropriate Sampling Sites

When working with complex models, it is easy to try to build a model more complicated than the data allow. For example, if a drug is metabolized and excreted unchanged, it is not possible to identify or determine a rate constant for excretion and for metabolism without measuring either drug or metabolite in urine. If the analyst attempted to model this overparameterized model with just drug-in-plasma data, the uncertainty (CV values, etc.) about the parameter values would be very high no matter how many data points were collected or how accurately they were measured. This is a problem in identifiability. The problem is to determine whether the minimum number of sampling sites for a particular model or a given number of sampling sites can adequately define a proposed model. There are a

number of approaches to this problem. For linear, time-invariant systems, the Laplace transform method is convenient, whereas the Taylor series method is a more general analytical method (45–47). Numerical approaches have been presented by Jacquez et al. (48, 49) with the development of the IDENT computer program. Another method is to simulate error-free data for the sample sites and the model chosen and “refit” these data. If the uncertainties in the parameters estimated are large (using numerous, error-free data), then an identifiability problem should be expected. The identifiability of a sample and model set should be determined during the initial experimental design stage. This can avoid considerable time and expense.

Determine Optimal Sampling Times to Reduce Parameter Uncertainty

Once the sampling sites have been identified, the next question is, at what times should the samples be collected. Without any previous knowledge of the model or system, sampling times are typically determined from intuition or from similar studies. Because of the uncertainty in the expected result, more samples are typically collected over as wide a range in time as possible. Once these first (pilot study) results have been analyzed, it is possible to make a more rational decision regarding the best sampling times. Some methods use the model selected and the parameter values first determined to obtain the best sampling times. The program SAMPLE, part of the ADAPT II package, uses the C- or D-optimality method. The result typically is one optimal sample time for each parameter to be estimated. Many investigators are uneasy about such a small sample number, thus additional samples may be included. By repeating the SAMPLE calculation with a range of parameter values, it would be possible to determine additional sample times. These times should give the “best” information about the parameters of interest.

Computer Programs

A large number of computer programs are available to perform the functions of mathematical modeling. Some of these are listed below. See <http://www.boomer.org/pkin/soft.html> for a more complete and up-to-date list.

1. ADAPT II is supplied as FORTRAN code for VAX VMS, MS DOS, and SUN UNIX systems. It performs simulations, fitting, and optimal sampling and includes extended least-squares and Bayesian optimization. Models can be expressed as integrated or differential equations using FORTRAN statements.

2. BOOMER is supplied as a compiled program for Macintosh and MS DOS systems. It performs simulation and fitting and includes Bayesian optimization. Models, integrated or differential equations, are expressed as a sequence of parameters.
3. IDENT2 and IDENT3 are provided as FORTRAN source code (IDENT2C is provided in C) for VAX VMS and other systems. It performs identifiability analysis.
4. MULTI programs by K. Yamaoka and colleagues (44) are provided as BASIC source code within the manuscripts. Different versions include fitting to integrated or differential equations, Bayesian analysis, and extended least squares.
5. NONMEM is provided as FORTRAN source code for UNIX, IBM, and other computers. The program performs nonlinear regression of individual or population data.
6. NPEM is a program for performing nonparametric expectation maximization.
7. SAAM II is provided as a compiled program for Windows or Macintosh systems and performs nonlinear regression analysis. It has a graphical user interface for model specification.
8. WinNonlin is provided as a compiled program for Windows systems and performs nonlinear regression analysis.

Materials of Construction for Pharmaceutical Equipment

Michelle M. González

Amgen Inc., Thousand Oaks, California, U.S.A.

INTRODUCTION

Materials required in the fabrication of equipment and associated systems dedicated to the production of pharmaceutical products should be capable of withstanding the temperature, pressure, and chemical corrosiveness of the product to ensure its purity and integrity. They also must meet a high degree of cleanliness to convey sterile and nonsterile products or solutions, particularly when it applies to their contact surfaces. Contact surfaces are “all surfaces exposed to the product or from which liquids may drain, drop, or be drawn into the product,” and solution contact surfaces are “the interior surfaces of the circuit used exclusively for supply and recirculation of cleaning and/or sanitizing solutions.”^[1]

For many years, pharmaceutical equipment manufacturing has relied predominantly in stainless steel, particularly the 316L type to meet the sanitary requirements of equipment and interconnecting systems such as piping and/or tubing, and in-line monitoring sensors, etc. However, with increased frequency, plastic materials are being utilized to meet the same requirements. Among the most notable materials in this group are the fluorinated plastics including polyvinylidene fluoride (PVDF), polytetrafluoroethylene (PTFE), or perfluoroalkoxy (PFA) resin,^[2] and thermoplastics such as polypropylene (PP). Additionally, elastomers such as ethylene-propylene-diene rubber (EPDM), “steam resistant” fluororelastomers (FKM), platinum-cured silicon (pt-Si), and Kalrez[®] perfluoroelastomers (FFKM) parts using compounds KLR-6221 and KLR-6230^[3] have also played a very significant role by providing sealing and resilient applications that meet the requirements of Code of Federal Regulations (CFR) Title 21, Foods and Drugs current Good Manufacturing Practices (cGMPs).

The objectives of this article are to offer a comparison between the technologies involved in the production of those materials and their current uses, particularly in process and support systems, and to compare their microbiological impact in the manufacturing of pharmaceuticals.

STAINLESS STEEL

Selection of Stainless Steels

Stainless steels are uniquely qualified for bioprocessing applications not only because of their long service life, availability and fabricability, but also because they are noncorroding, noncontaminant, can be polished to very smooth finishes, are strong and rigid, can withstand heat and chemical sterilization treatments, and are easily welded. With more than 70 standard types of stainless steel produced, the industry's workhorse is the austenitic 18–8 (18% chromium, 8% nickel) group which includes types 304 and 316 and their L or low carbon content variations. With concerns for higher corrosion resistance, the new and better low carbon superaustenitic stainless steel AL-6XN (6% molybdenum) and the nickel-based alloys, Hastelloy B and Hastelloy C, are becoming notoriously important in the fabrication of vessels, piping, tubing, and fittings (see Table 1). Finally, the cast stainless alloys such as CF-8 (similar to 304), CF-8M (similar to 316), and CF-3M (similar to 316L) utilized in pumps, various types of valves (particularly ball type), and fittings also occupy a prominent position in the industry.

Standards and Codes

In some pharmaceutical industry circles, there is the belief that the stringent specifications that rule pharmaceutical processes have no comparison with the food and dairy industries.^[4] Actually, almost the reverse is true; the present standards and specifications for tubing fabrication and their product/solution contact surfaces, as well as the installation of systems, have their origin in the dairy industry through the well-recognized 3-A Sanitary Standards and Accepted Practices (Numbers 33-00, and 605-04). Published by the International Association for Food Protection (IAFP), formerly known as the International Association of Milk, Food and Environmental Sanitarians (IAMFES), these standards and practices cover: first, the sanitary aspects of polished metal tubing used to conduct dairy products in processing lines or systems that also may include sanitary fittings, and secondly, the cleaning of rigid solution lines and the clean-in-place (CIP) units that circulate the preinse, rinse,

cleaning solutions, and postrinse liquids used for cleaning and sanitizing the product pipelines and process equipment.

As the pharmaceutical industry advanced, the development of new technologies to make or modify products by microbial and biochemical processes using living organisms or substances from those organisms (Biotechnology) increased the need for more stringent regulations. Many of these regulations were related to equipment cleanability and sterility, standardization of manufacturing methods, and integration of standards covering vessels, appurtenances, and equipment necessary for the industry. The American Association of Mechanical Engineers (ASME), through its Council on Codes and Standards (CSS) and a directive to the Board on Pressure Technology, initiated the creation of what is now known as the Bioprocessing Equipment (BPE-2002/BPE-a2000), an American National Standard. This Standard directly (or by reference) covers requirements for materials, design, fabrications, examinations, inspections, testing, certifications (for pressure systems), and pressure relief (for pressure systems) of vessels and piping for bioprocessing systems, including design for sterility and cleanability (Part SD), dimensions and tolerances for automatic welding and hygienic clamp tube fittings (Part DT), material joining (Part MJ), interior surface finishes (Part SF), and equipment seals (Part SG). Requirements of this Standard apply to all parts that contact the product, raw materials, or product intermediates during manufacturing, development, or scale-up, and all equipment or systems that are a critical part of product manufacturing, such as water-for-injection (WFI), clean/pure steam, ultrafiltration, and intermediate product storage.

While ASME BPE-2002 addresses requirements applicable to the design of equipment and components, other codes and standards define specific requirements for the manufacturing of components critical to the processes and support utilities, particularly piping, tubing, and fittings. The most notable are: American Society for Testing and Materials (ASTM) A269 “Standard Specification for Seamless and Welded Austenitic Stainless Steel Tubing for General Service,” ASTM A270 “Standard Specification for Seamless and Welded Austenitic Stainless Steel Sanitary Tubing,” and ASTM A312/ASME SA312 “Standard Specification for Seamless and Welded Austenitic Stainless Steel Pipe.”

Product and/or Solution Contact Surface Finishes

Surface finishes are all interior surface finishes accessible and inaccessible, that directly or indirectly come in contact with the designated product in BPE and distribution system components. Surface finishes have been qualified and quantified utilizing various names and measurement units such as Grit Numbers, USA Finish Numbers, Common Name, Ra ($\mu\text{in.}$), Ra (μ), Rmax (μ), Rmax (μ), RMS, ISO number, etc.^[5] Each of these roughness parameters have met their purpose but this variety of systems has also created broad and sometimes overlapping measurement ranges resulting in a high degree of confusion (see Table 2).

The need for a universally recognized and accepted surface roughness specification and measurement standard has become necessary and a final criterion has been determined by the standard Ra value. This standard known as Arithmetic Average Roughness, is defined by

Table 2 Surface measurements comparison

RMS ($\mu\text{in.}$)	RMS (μ)	Ra ($\mu\text{in.}$)	Ra (μ)	Grit size
80	2.03	71	1.80	80
58	1.47	52	1.32	120
47	1.20	42	1.06	150

14	0.36	12	0.30	320
		4–8		320 EP
		10		400

(From DCI, Inc., Stainless Steel Processing Equipment. Material/Weld FINISHES, pamphlet.)

ANSI/ASME B46.1 “Surface Texture—Surface Roughness, Waviness and Lay” as “the arithmetic average height of roughness component irregularities from the mean line measured within the sample length (L)” (see Fig. 1). The derivation Ra is usually expressed in $\mu\text{in.}$ and measured with profilometers and/or borescopes.

Electropolished (EP) Finishes

Because the pharmaceutical industry requires smoother product/solution contact surfaces to achieve a purer product with less danger of bacteria growing in surface defects or cross-contamination of one product with another,^[6] in addition to purely mechanical finishes, sanitary tubing and components are also available in highly polished surfaces.

These surfaces are achieved by electropolishing also known as “chemical machining” and/or “reverse plating,” an electrochemical process far superior to any available mechanical process for the removal of surface imperfections in stainless steels. Electropolishing levels and brightens the material surface by anodic dissolution in flowing mixed acid solutions, sometimes with organic additives, (electrolyte) and a cathode that is pulled through the inside of the tube or component (anode). When the proper combination of electrolyte current temperature is attained, the high points of surface irregularities (or high current density areas) are selectively removed at a greater

rate than the remainder of the surface resulting in improved surface measurements (see Figs. 2 and 3).

In addition to appearance, EP products offer other advantages such as an extremely smooth surface which minimizes the adherence of debris, an increased chromium to iron ratio which improves corrosion resistance, the creation of a passive layer that is free from iron contamination, improved ability to visually detect surface defects, and improved mechanical property performance through the minimization of stress risers.

Joining Techniques

Requirements for the joining of BPE including vessels and tanks [built to ASME Boiler and Pressure Vessel Code (BPVC), Section VIII, Division 1], pumps, piping (built to ASME B31.3), tubing, and fittings, are described in Part MJ of the ASME BPE-2002 and are limited to process systems that contact bioprocessing products or product-process streams. Welding procedures for pressure vessels, tanks, piping, and hygienic tubing systems shall be qualified in accordance with ASME BPVC, Section IX.

Because tubing systems occupy a most notorious place in the construction of bioprocessing facilities, focus has been placed upon the prevalent method for joining these systems. Connections between tube and tube or tube and fitting and even tube/fitting to equipment can be accomplished by diverse means. However, the use of mechanical joints where impurities entrainment may occur, such as flanges, threaded joints, or even hygienic clamp type joints must be minimized. Thus, systems shall preferentially be joined using square butt-welding practices only because they present the lowest risk of contamination.

Automatic Orbital Welding

Typically, square butt-welded tubing joints are made using automatic orbital welding equipment which fuses the thin wall tubes and fittings together in a totally inert environment without the use of filler materials (auto-genous weld).^[7] Essentially, an arc established between a tungsten electrode (installed in a rotor within the weld

**Fig. 1** Pictorial display of surface texture.

Fig. 2 Before electropolishing the mechanically polished surface of stainless steel appears rough as viewed under $1000\times$ magnification on Scanning Electron Microscope.

head) and the tubing accomplishes the fusion weld. This process consists of a series of spot welds in which the main welding current penetrates the material and the back-ground current chills the puddle. The quality of the fusion joint that is made by this equipment is predicated on the use of two pieces of material of the same thickness and grade or type; therefore, great care must be exercised in material and component selection.

The actual welding process requires the tube/tube or tube/fitting to be placed in a welding head (see Fig. 4) provided with clamping jaws to securely hold the parts in

Fig. 3 After electropolishing the same surface appears smooth as viewed under $1000\times$ magnification on Scanning Electron Microscope.

Fig. 4 Automatic orbital welder in the process of joining two long tangent stainless steel fittings.

position and in alignment with the tungsten electrode contained within the head. The entire area to be welded is then enclosed in the welding head, forming a chamber that is filled with shielding gas, usually argon, to prevent oxidation of the welded material during the weld sequence. Meanwhile, the inside of the tube is purged free of oxygen allowing the entire area to be completely covered with argon gas. The weld cycle is preprogrammed and set in the machine, making the entire operation completely automatic. The electrode orbits around the weld seam on an internal gear while the head remains stationary and when the rotation is completed, the head can be opened and immediately removed from the welded section.

Stainless Steel Passivation

Passivation is a postweld treatment and/or cleaning process used to restore (by introduction of oxygen) the thin chromium oxide (with some oxides of iron and nickel) film or passive layer that forms on stainless steel naturally when in contact with air. Methods and tests for cleaning and passivation of critical water, product, and process systems are described in ASTM A380 "Standard Practice for Cleaning and Descaling Stainless Steel Parts, Equipment, and Systems."

Passivation removes/dissolves free iron and other anodic contaminants from the surface of corrosion-resistant parts leaving chromium and iron oxides as the primary metal components. Because welding disturbs

the passive layer by reducing the chromium and increasing the iron, thus altering the chrome/iron ratio (measure of corrosion resistance), upon completion and approval of the weld, the weld surface and adjacent boundary area must be brought back to a passive state. Also, certain normal operating conditions in typical WFI, reverse osmosis (RO), deionized water (DI), clean/pure steam, some process systems, and in some rare cases, CIP systems often lead to formation of the most prevalent form of self-catalyzing corrosion called “rouge” which is a colloidal form of iron oxide containing chromium and nickel in various forms. This problem may be accentuated by the use of high temperature, aggressive process chemicals, ultrapure water, and can be overcome only by restoring the surface to its passive state.

Some of the most recognized tests to detect, measure, and quantitate the chrome/iron ratio and to ensure that a passive layer has been established are the Ferroxyl Test for Free Iron, X-Ray Photoelectron Spectroscopy (XPS) or Electron Spectroscopy for Chemical Analysis (ESCA), and Auger Electron Spectroscopy (AES).

PLASTICS

ASTM defines a plastic as “a material that contains as an essential ingredient one or more organic polymeric substances of large molecular weight, is solid in its finished state, and, at some stage in its manufacture into finished articles, can be shaped by flow.”

As the pharmaceutical and biotechnology industries confront challenges such as increased competition, consolidation, globalization, high R&D costs, and demanding manufacturing standards and guidelines, the need for the use of alternative materials of construction becomes a more significant issue. Despite of the many advantages of stainless steel, the wide availability of thermoplastics and fluorinated plastics offering lower initial costs, less weight, complete resistance to corrosion, elimination of the passivation process, and extremely smooth internal surfaces have increased their application, particularly in systems such as purified water (PW) distribution loops and other processes.

Fluoropolymers or Fluorinated Plastics

Fluorinated plastics are thermoplastic paraffinic polymers where the hydrogen has been replaced by fluorine and, in some cases, chlorine.

PVDF—Approval FDA 21 CFR 177.2510

PVDF is a strong, abrasion resistant, and wide temperature service range (−40–284°F) fluorocarbon material. Similar

to PTFE, with the exception of not being fully fluorinated, it is a relatively inert material resistant to permeation of gases contributing little in the way of contamination to pharmaceutical water. It is chemically resistant to most acids, bases, and organic solvents and is ideally suited for handling wet or dry chlorine, bromine, and other halogens, but is unsuitable for handling strong alkalis, fuming acids, polar solvents, amines, ketones, and esters. It has a high tensile strength as well as a high heat deflection temperature. PVDF offers an extremely smooth surface finish (between 6 Ra and 8 Ra) and can be readily joined by the fusion process (free of internal beads or crevices), threading, or flanging.

The focal point of a sanitary system is its water, which has to be pure. A useful definition of high purity water is “water that has been purified to a degree not found in nature.” High purity water has to meet the drinking water standards of the U.S. Environmental Protection Agency (EPA) for feedwater of the compendial waters (those used as an ingredient in pharmaceutical products), United States Pharmacopeia (USP) PW, and USP WFI. Because of its high purity, low surface and joint extractables, and elevated temperature cleanability, natural unpigmented PVDF has become the most important alternative material for use in PW distribution systems.

PVDF, however, has been used primarily in water systems that operate at ambient temperatures. There is some skepticism in the use of PVDF in hot (176°F) WFI distribution loops, mainly because it has been observed that exposure to heat will discolor the material. The discoloration is the result of alterations to the chemical structure of PVDF on the atomic scale. Testing of piping samples revealed that leaching was insignificant and welds remained strong after 1 to 16 week exposures to hot ultrapure water.^[8]

PTFE—Approval FDA 21 CFR 177.1550

Introduced by DuPont as Teflon® in 1950, PTFE is a fluoroplastic resistant to practically every known chemical or solvent and possesses the highest useful temperature limit (−200–500°F) of commercially available plastics, has an exceptionally low coefficient of friction, high impact strength, and low surface energy. Usual processing techniques like injection molding are not possible with PTFE; it must be compression-molded into block form and then machined into a finished product. PTFE resin is pressed into shapes under high pressure at room temperature and then heated to 700°F to complete the molding (sintering process) and adjust the crystalline content.

Because of its elastic recovery properties, PTFE, a self-lubricating compound, is used in sealing and flexing applications such as sanitary seals, valve diaphragms,

o-rings in mechanical seals, and seals and seats of stem and rotary valves such as ball valves. It is also commonly used as a liner or coating material for valves and pumps for the pharmaceutical industry.

PFA resin—Approval FDA 21 CFR 177.1550

Of the melt-processible fluoropolymers, which are the most suitable for tubing, PFA provides the extreme thermal and chemical resistance required in the pharmaceutical processing. PFA, however, does not have the physical strength of PTFE at elevated temperatures and must be reinforced or designed with thickness to compensate for its softness. Tests have shown that among materials such as stainless steel, glass, silicon-coated glass, PP, and PVDF, even when proteins and micro-organisms were added to more efficiently wet test surfaces, PFA was the least affected by contaminants and biofilm growth.^[9] PFA has been proven in CIP–SIP operations, ultrapure water, WFI, and pharmaceutical applications.

Thermoplastics

Thermoplastics have a defined melting point; they can be melted, cooled, and remelted without destroying the physical or mechanical properties of the polymer.

PP—Approval FDA 21 CFR 177.1520

PP, a polyolefin polymer, is probably one of the most economical and widely used thermoplastics. A crystalline polymer with heat deflection temperature ranging from 195 to 240°F (higher than other common plastics) offers as its key properties, a high heat resistance (for piping, an upper limit of 212°F), a specific gravity of 0.91 if unmodified (the lightest of the most common thermoplastics), stiffness, and chemical resistance to caustics, solvents, acids, and other organic chemicals. Its use is not recommended with strong oxidizing type acids, detergents, low boiling hydrocarbons, alcohols, and some chlorinated organic materials. Because PP is a relatively inert material and contributes little in the way of contamination to pharmaceutical water, it is highly suitable for piping systems. PP also has proved to be an excellent material for laboratory and industrial drainage where mixtures of acids, bases, and solvents are involved. PP is available in schedules 40 or 80 for pressure service and can be joined by socket solvent welding, thermo-seal fusion process, threading (Sch. 80 only), or flanging. The plastic pipe industry recognizes that PP compounds containing more than 2.5% carbon black can have an outside service life of more than 25 yr.

Sealing Materials

Seals are those elements that create or maintain process boundaries between system components and/or subassemblies in order to ensure system integrity in validated process and utility systems. Seals must be biocompatible (able to be in contact with bacteria or mammalian cells without interfering with their metabolism or ability to live and multiply), must be corrosion and permeation resistant, their surface finishes must be free of molding imperfections and foreign matter on surfaces within the sealing area, and shall not generate particulate that may entrain the product.

Elastomers (materials that can be stretched or compressed repeatedly and, upon immediate release of stress, will return to their approximate original size) are long chain copolymers or terpolymers (two or three different monomers in one chain) that contain adequate cross-links among individual chains. Fluorinated elastomers are more stable than hydrocarbon or silicon elastomers because carbon–fluorine bonds are approximately 30% stronger than carbon–hydrogen bonds. There are five major FDA (21 CFR 177.2600) compliant elastomers used in the pharmaceutical industries: EPDM, FKM, platinum-cured silicon, and FFKM KLR-6221 and KLR-6230. Of the compounds used for medical seals, FFKM have the broadest range of chemical resistance of any other elastomeric material and are readily formable into many standard and custom seal configurations.^[10]

CONCLUSION

It is very clear to see that the biotechnology industry demands special care and attention in the selection of materials for the product contact surfaces as well as the solution contact surfaces. The emphasis has been placed principally in the cleanliness and corrosion resistance issues. To these purposes, a whole segment of the industry dedicates considerable time and effort in R&D for new materials and applications. Awareness and adherence to present codes and regulations as well as knowledge of new and advanced technologies are the keys to successful completion of design and engineering of systems utilizing these very valuable resources.

MANAGEMENT OF DRUG DEVELOPMENT

James E. Tingstad

Tingstad Associates, Green Valley, Arizona, U.S.A.

The most successful new drug-development programs require competent, caring, people-oriented leaders at all levels. Overwhelming social science data show that this approach will optimize productivity, efficiency, and creativity, while fostering employee growth, enthusiasm, cooperation, and loyalty.

THE DRUG DEVELOPMENT PROCESS

Before addressing the components of good management, here is a review of the basic new drug (new chemical entity or NCE) development process.

Brief Overview

The NCE works its way through the following groups before it can be marketed:

Synthetic Chemistry → Pharmacology → Toxicology → Pathology →
Regulatory Affairs [Investigative New Drug (IND) application] →
Product R&D → Clinical Research → Regulatory Affairs [New Drug Application (NDA)] → Approval by government regulatory agency

Additional Important Contributors

Other involved departments/disciplines that are equally important as the above groups include Analytical Chemistry, Biochemistry, Biopharmaceutics/Pharmacokinetics/Drug Metabolism, Chemical Pilot Plant, Experimental Engineering, Packaging Development, and Statistics. Additional significant contributors include Purchasing and Quality Assurance/Documentation.

Post-NDA Departments

After NDA approval, non-R&D functions—after being partially involved at various stages of NCE development—take over, including Chemical Manufacturing,

Engineering, Marketing, Packaging, Pharmaceutical Manufacturing, Quality Control, and Sales.

Departmental Responsibilities

Companies are organized differently; for example, the various engineering responsibilities may be in one or more departments. A brief description of typical functions follows:

- Synthetic chemistry synthesizes NCE candidates for pharmacological testing.
- Pharmacology examines the *in vivo* activity of the NCE in animals (1).
 1. For economic reasons, activity is determined in animals before safety, whereas in humans, preliminary safety studies need to come first.
 - Toxicology determines the “macro” negative effects of the NCE in animals.
 - Pathology examines the “micro” negative effects of the NCE in animals.
 - Product R&D designs a simple, preliminary dosage form for initial clinical trials (2).
 2. Additional dosage-form development is deferred until safety/activity experiments in humans show promise. Eventually, scale-up experiments are conducted in cooperation with Pharmaceutical Manufacturing.
- Clinical research determines the safety and efficacy of the NCE in humans.
 - Phase I examines small-dose tolerance and safety in a limited number of young adult, usually male, volunteers.
 - Phase II, involving hundreds of patients, investigates efficacy, dosage, and prominent side effects.
 - Phase III, utilizing thousands of patients, broadens Phase II experiments and determines safety, efficacy, and marketability.
 - Phase IV, conducted after regulatory approval and marketing, investigates additional medical uses.

- Regulatory Affairs works closely with all relevant organizational units and is the primary contact with government regulatory agencies.
- Analytical Chemistry develops stability-indicating assays for NCEs and identifies/quantifies impurities; cooperates with Product R&D on product stability studies.
- Biochemistry determines, among other experiments, the cell-level effects of NCEs.
- Biopharmaceutics, Pharmacokinetics, and Drug Metabolism examines the absorption, distribution, metabolism, and elimination of NCEs.
- Chemical Pilot Plant produces NCEs for R&D groups.
- Experimental Engineering helps design new processes and equipment.
- Packaging Development develops containers for new products with stability and consumer issues in mind.
- Statistics is involved in planning and interpreting many R&D experiments.
- Purchasing works with R&D to ensure consistent, high-quality raw materials from vendors.
- Quality Assurance/Documentation monitors procedures and records to comply with government-regulated Good Laboratory and Manufacturing Practices.
- Chemical Manufacturing supplies the bulk NCE to Pharmaceutical Manufacturing.
- Engineering offers process/equipment services to post-NDA groups.
- Marketing, in cooperation with Sales and Advertising, determines the overall strategy for supplying NCE products to primary customers (physicians and other healthcare professionals).
- Packaging packages and labels manufactured drug products for sale.
- Pharmaceutical Manufacturing produces finished drug products for consumer use.
- Quality Control monitors the quality and stability of manufactured/marketed drug lots.
- Sales supplies products to customers.

Departmental Interactions

It's important for managers and laboratory workers to meet with colleagues from other departments to learn about interrelations and interdependencies and to use that knowledge to ensure mutual understanding, respect, support, and cooperation. Here are examples:

Sales \longleftrightarrow All R&D groups

R&D managers and laboratory workers should be encouraged to spend a day or two (one-on-one) with a salesperson "on the road," for two primary reasons:

1. R&D individuals can observe first hand the results of their labors.
2. Salespersons can learn important, relevant scientific facts about what they are selling and can directly inform the R&D person about problems their customers experience.

Synthetic chemistry \longleftrightarrow Biopharmaceutics

Oral absorption data can help lead synthetic chemists in the most promising directions for NCE variations.

Synthetic chemistry \longleftrightarrow Product R&D

Formulators usually prefer the most water-soluble form of an NCE; this can conflict with Synthetic Chemistry and Chemical Manufacturing's interest in high yields.

Biopharmaceutics \longleftrightarrow Pharmacology

Interactional benefits go both ways, but Biopharmaceutics can help pharmacologists determine whether lackluster potency is attributable to inherent inactivity or poor oral absorption.

Product R&D \longleftrightarrow Toxicology

True event: Product R&D helped Toxicology determine that the apparent intestinal irritation of an orally administered NCE was caused not by the drug, but by the "innocuous" solvent (glycerin).

Analytical chemistry \longleftrightarrow Quality control

Analytical Chemistry develops stability-indicating assays for R&D, then transfers them to Quality Control when the product is marketed. Too often these groups are at loggerheads concerning what is an adequate, efficient assay procedure for the NCE. Management's mutual respect and cooperation, plus voluntary temporary interdepartmental transfers, can usually minimize these difficulties.

Pharmaceutical manufacturing \longleftrightarrow Product R&D

1. These two groups need to interact at the appropriate stages in new drug development (especially scale-up) to ensure that a dependable, high-quality product can be consistently and economically manufactured.
2. Hands-on Manufacturing employees may feel most comfortable interacting with R&D scientists at the B.S./Associate degree level rather than at the Ph.D. level.

3. Product R&D laboratory workers at all educational levels should spend their first month or two in Pharmaceutical Manufacturing—working hands-on rather than just observing.

Marketing ↔ All R&D groups

True event: A Marketing executive was touring R&D laboratories and asked a key synthetic chemist working on antibacterials what she thought was the most important quality in an antibiotic after therapeutic activity. She replied, “lack of bacterial resistance.” When the executive emphasized that Marketing was most concerned about lack of side effects, the scientist said, “No one ever told me that.”

Quality assurance and documentation ↔ All R&D groups

Quality Assurance and Documentation should be thought of—and think of itself and operate accordingly—as helpful and supportive, not punitive.

Experimental engineering/product R&D ↔ Pharmaceutical manufacturing

True events:

1. Experimental engineering and Product R&D developed a computer-controlled automatic lyophilization process that was then transferred to Pharmaceutical Manufacturing.
2. Air-suspension particle/tablet coating and electronic monitoring of Pharmaceutical Manufacturing’s tablet presses improved product quality and manufacturing efficiency.

DEVELOPING LINE-EXTENSION PRODUCTS

Once the first NCE product has been approved by the government regulatory agency, additional products (Product Line Extensions, or PLEs) are often developed. Requests for PLEs usually come from Marketing and Sales, but ideas can come from any employee/department, particularly from Product R&D. Regulatory approval of most PLEs is less demanding than for NCEs, e.g., there are fewer safety and clinical experiments.

SUCCESSFUL MANAGEMENT OF DRUG DEVELOPMENT

Successful management consists of a series of thoughts, attitudes, feelings, and skilled practices, not simply (and

counterproductively) an “I-am-the-boss-so-do-what-I-say” culture.

Characteristics of a Fertile R&D Work Environment

Psychiatrist Abraham Maslow (1) emphasizes that managers should not be sculptors (molding/forcing/shaping workers) but farmers who create a fertile work environment wherein all employees can learn, grow, and do their best. R&D managers can optimize group spirit, cohesiveness, innovation, and performance by looking at the team as a circle (in which everyone has a significant contribution to make), and not as the usual organizational pyramid with the boss at the top.

Here are characteristics of a fertile R&D work environment, starting with six cornerstones.

- **Ethics**—This is noted first for obvious reasons.
- **Empathy**—Empathy is the key to proper treatment of hands-on workers, e.g., managers should ask themselves how they would want their boss to treat them.
- **Respect**—Feeling respected (valued) as a unique person and as a contributor to group success is as important as anything in the workplace.
- **Trust**—This is an identical twin to respect. Without mutual trust, two or more people cannot survive a joint effort. The manager’s genuine trust of employees as well intentioned, responsible adults is crucial to an efficient, productive work atmosphere.
- **Caring**—Managers need to have a genuine concern for employees’ personal and professional well-being.
- **Communication**—Keeping employees informed fosters feelings of importance and “being in on things.” Managers who listen carefully and inform abundantly will soon be surrounded by good communicators.
- **Sense of Purpose**—The manager and group members need to know how their department fits into the R&D division.
- **Commitment**—Everyone has a strong commitment to the long-term health of the division and to harmonized company, R&D, group, and personal goals.
- **Competence and Dedication**—Group members are competent and confident in each other’s ability and dedication.
- **Urgent but Well-reasoned, Goal-Focused Activity**—Activity is goal-focused, with the general work pace being a healthy blend of urgency and contemplative, well reasoned, deliberate progress.
- **Involvement**—Productivity, personal growth, and morale will be high if everyone feels involved in the

planning, decision-making, and movement of the department toward its goals.

- Individuality—Everyone wants to be treated as an important, unique individual.
- Acceptance—Related to individuality, each person is valued just as they are; idiosyncrasies are tolerated, even appreciated, because variety is the “spice of life,” and no one is perfect.
- Civility—“Good management starts with good manners, society’s means of ensuring consideration of others as people” . . . Anonymous.
- Agreeableness, Amiability, Friendliness—These are potent antidotes for nervous tension and anxiety and create as much tranquility in a work environment as civility.
- Honesty, Candor, Openness—If trust is basic to all good things in human relationships, honesty, candor, and openness are basic to sustaining/strengthening those relationships.
- Stability, Security, Predictability—The manager needs to be ethical, fair, and consistent without being inflexible. This minimizes uncertainty and anxiety and makes employees feel safe and secure. More energy can then be focused on productive work.
- Cooperation—When co-workers respect and care for one another and when all people feel safe and secure about their “place in the sun,” the stage is set for cooperation rather than for competition, for mutual esteem and pride rather than for envy.
- Recognition—Everyone is recognized for his or her accomplishments and value to the organization. Consequently, they feel good about themselves, their colleagues, their boss, and the corporation.
- Thoughtfulness (Consideration for Others)—It has been said that nothing is more contagious than nervous tension, but surely thoughtfulness must run a close second. This can take many forms, but it generally involves getting outside oneself, being significantly oriented toward others rather than solely toward oneself. It means giving rather than taking.
- Genuineness, Realness—A quality work environment helps workers feel safe, secure, and accepted, thus encouraging them to be themselves, “warts and all.” This reduces facades, protectiveness, and defensiveness, and allows people to focus their energy on productive work.
- Independence and Interdependence—When employees are valued for their basic worth and respected for their individuality, they develop a strong sense of independence. Consequently, they will have little need to “throw their weight around” or assert their individuality at the expense of others. When people feel good about

themselves and receive emotional support from colleagues, they develop a strong sense of both independence and interdependence.

- Cohesive Group Spirit—Under good management, a group develops a close, family-type working relationship in which individual members care for, trust, and respect, and have confidence in one another.
- Deference—If the aforementioned characteristics are operative and the manager seeks advice from and defers to hands-on workers, group members will defer to one another’s expertise and judgment when appropriate.
- Pride (but not Arrogance)—Realistic pride in oneself and in the work group strengthens group cohesiveness and individual self-confidence and fosters a “can-do” attitude toward innovation and technical challenges.
- Loyalty and Enthusiasm—When colleagues work at being civil and respectful, loyalty and enthusiasm will arise spontaneously. As Napoleon said, “An army’s effectiveness depends on its size, training, experience, and morale . . . and morale is worth more than all the other factors combined.”

Honorable and Successful Management Practices

The following are specific suggestions for managing drug development. Two quotes say it all:

Honor is the quality of personal integrity. It is won slowly by a lifetime of small decisions where one places the virtues of compassion and justice ahead of his own advancement. — *Anonymous*

The only way to be a successful manager is to learn to behave like one. — *Jay Hall*

Behaving Ethically

This is listed first because everything must be based on consistent ethical principles and behavior. R&D managers work in an especially complex environment: they hold great power and interact in complicated ways with hands-on workers, peers, upper management, customers, local and national government agencies, and citizen groups. R&D managers also face a unique situation because often results must be taken on faith. Most projects involve extensive experimentation and complex interpretation; some involve equivocal results. Managers must:

1. Trust the competence and honesty of laboratory workers, and
2. Make honest use of the group’s experimental results.

The leader is primarily responsible for the ethical attitude, behavior, and performance of the department. Here are three ways to ensure success:

1. Set a good example—The manager sets the tone for any group, acting as a role model. When employees observe that the boss is consistently ethical, they will set similar high standards for themselves.
2. Minimize unethical conformity and group-think—Peer pressure dominates most teenagers (“All my friends do it ...”), but adults must resist the slightest unethical behavioral norms.
3. Create a safe, stable, predictable work environment—Unless they are pathological, people suffer ethical lapses out of confusion, fear, and insecurity, not out of evil. When workers are afraid of punishment or dismissal if schedules aren’t met, work tends to become sloppy. When R&D vice-presidents fear their jobs are in jeopardy, they might manipulate the information going to corporate management so that their organization will look good.

In summary, leaders need to have the personal qualities of candor, genuineness, and integrity. If not, they are in danger of becoming manipulators of people and situations.

Empathizing (The Golden Rule of Management)

As one of the six cornerstones of successful management, the importance of empathy cannot be overemphasized. Before managers make decisions affecting workers (read “almost all decisions”), they need to remember the Golden Rule of Management: How would I like to be treated? This safeguard on managerial behavior is nearly infallible; here are two examples:

Promotions

Case A: An experienced laboratory scientist believes that he deserves a promotion to the next grade. He raises the issue with his supervisor; she tells him that he has potential, but she is not yet convinced that he has sufficiently proven himself. Nineteen months later he is promoted.

Case B: An experienced research scientist’s manager comes into his laboratory and informs him that he has been promoted to the next grade. The scientist is delighted but surprised; he didn’t expect promotion for another year. The manager says that it may be a little early, but based on his performance and obvious potential, she believes that he deserves to be promoted now.

Reading this example, managers need to play the role of the laboratory scientist and ask themselves how would they would like to be treated by their boss; and would A or B elevate their spirit and incentive to work hard?

Treating employees as well-intentioned, responsible adults

Case A: Laboratory workers discover that, inadvertently, they are not in compliance with several Good Laboratory Practices regulations. When they inform the manager, he calls a department meeting, scolds all of them, orders them to shape up or else, and demands a full report within 3 days.

Case B: When the manager is informed of the GLP violations, he calls a department meeting, thanks them for alerting him to the problem, and asks them if he can be of any help; who would like to take charge of correcting the situation; and what deadline should be set so that he can reassure his boss.

Again, managers should play the role of laboratory workers and ask themselves how they would like to be treated, A or B.

Communicating

Here are two quite different definitions of communication:

1. The goal of communication is to persuade the listener to agree with the speaker. In this case, one gives little thought to the other’s position. Most time and energy are spent thinking about what to say next rather than listening.
2. The purpose of communication is to create understanding. Here the emphasis is on listening, accepting differences of opinion, and freely expressing feelings.

Many sounds (street noise, small talk at a party) are assimilated through a process of hearing. This is primarily a physical phenomenon, with only a small mental element and virtually no emotional component. But when someone tries to communicate something they consider important, hearing becomes inadequate; instead, the other person needs to listen to and understand what they have to say. Now the process requires three components—physical, mental, and emotional—and becomes much more complex.

Generalizations aside, managers need to look at how communication skills apply to their job. First, the leader needs to communicate to employees the kind of person he or she is. Good working relationships, the cornerstone of good performance, depend on people getting to know one

another. It is the manager's responsibility to initiate and encourage the communication process that brings about understanding. For example, he should meet at least once a year with each employee to find out:

- How things are going, personally and on-the-job;
- What is good and what is bad about the work environment;
- Always refer to the department as "ours," never "mine";
- Always say, when introducing a group member to someone else, "she works with me," never, "she works for me";
- Encourage being called by his first name, because hierarchy tends to disappear when people are on a first-name basis;
- Try to be the first one at department meetings; too many managers, for various reasons, wait until everyone else is assembled and then walk into the room. Making people wait is an inherent sign of disrespect, intended or not;
- Keep employees informed by posting all nonconfidential memos and notices on a large bulletin board under the categories of "urgent," "new," and "old." These actions are not gimmicks as long as they represent a sincere effort by the manager to communicate clearly and emphatically that everyone in the group is important.

Another valuable communication tool is seldom used—anonymous employee opinion surveys conducted by the manager, in addition to those of the Human Resources department. Annually, workers are asked to submit to the secretary their answers for three questions. The secretary then combines all responses:

1. What I like about my job;
2. What I don't like about my job; and
3. What my boss can do to make things better. Then (and most important), the manager should call a department meeting and ask the group to decide the priorities for improving the work environment.

Organizing

Hands-on laboratory workers

Experts agree that the number-one problem in any corporation is the underutilization of employees. This stems from management's failure to appreciate their intelligence and potential. Douglas McGregor (2) says that most people enjoy working and, given the chance, prefer to exercise self-direction and self-control. They are highly motivated, seek responsibility, and can be a major positive force in company operations if management allows them.

For example, too often Ph.D.s (scientists) are informal project leaders when B.S.-level laboratory workers (associate scientists) can do that job very well, allowing the Ph.D. to act as theoretical science advisors for several project teams. Then Laboratory Assistants (Technicians or Assistant Scientists) with high school diplomas or 2-year degrees can do most of the daily laboratory work with relatively little supervision rather than being treated as a "pair of hands." When employees feel respected and are encouraged to grow and take as much responsibility as possible, they will consult with higher-level scientists when necessary to minimize mistakes and to ensure group success.

First-line supervisors

Group Leaders/Section Heads should be responsible for approximately 15 laboratory workers and should think of themselves as supervisors, not superscientists. The nonsupervisory Ph.D.s should make most of the broad scientific decisions; the Group Leader/Section Head should concentrate on becoming a successful manager of people.

Management

Most organizations have too much management; the number of supervisors at all levels should be minimized.

Supervising

Douglas McGregor says that the supervisor should act as a helper, teacher, consultant, and colleague. Rarely should she assume the role of authoritative boss. Tom Peters agrees, saying "Leaders are servants." Hands-on workers produce results; the manager's primary job is to support them and remove obstacles that prevent them from doing their best. The best supervisor will ask workers what she can do to help; rather than making sure the jobs get done, she assists the workers in doing so.

Many leaders feel this approach reduces their organizational power (using "power" in the good sense), but the exact opposite is true.

1. The manager "sees over" more clearly because discussions with employees will sharpen the view of the situation for everyone.
2. Control and communication are enhanced because employees will interact frequently with a manager who is viewed as a source of help rather than as a giver of orders.
3. Treating employees as competent, responsible adults will greatly increase her influence with them.

Controlling

Originally, controlling meant running a tight ship; the boss watched over everyone and everything, told employees what to do and when to do it, and made all the important decisions himself. But this made the leader and hands-on workers antagonists, resulting in the manager knowing relatively little about what really went on in the trenches. In contrast, appropriate (nonauthoritarian) control means emphasizing employees' self-control simply because most people are trustworthy. This is especially true in R&D organizations in which the emphasis is on high technology, creativity, and innovation.

Peter Drucker, Tom Peters, and Douglas McGregor agree:

1. Drucker says that to be productive, workers need to have control over their work; control is a tool of employees and must never be their master.
2. Peters calls this the control paradox: less is more. Less central control and more genuinely delegated self-control for those closest to the action translates into tighter overall control.
3. McGregor believes that successful supervision is largely dependent on the manager's ability to predict and control human behavior, and the essence of control is selective adaptation. People control the physical world around them, not by expecting nature to do their bidding, but by adjusting their actions to natural laws. For example, humankind does not control surface water by commanding it to flow uphill; rather, people dig channels, adjusting to the fact that water obeys the law of gravity.

Similarly, effective management control consists of channeling workers' energies, interests, and capabilities into activities that meet organizational objectives. Management controls the work force by adjusting its decisions and actions to the realities of human nature, and not by telling people what to do and expecting blind obedience.

Delegating

Managers should delegate because employees like, want, and need to do things their own way. The wise leader assigns research projects only after consulting with laboratory workers, preferably at a department meeting, because bench scientists tend to have a much better feel than the manager concerning who has the time; who is most qualified; and how best to divide up responsibilities.

Also, employees feel more respected and involved when they are part of the work-assignment process.

Delegation, not relegation

Since the biggest waste in any organization is underutilization of employees, delegation makes sense. Unfortunately, too many leaders confuse delegation with relegation. Delegation means assigning responsibility and authority to a representative. Relegation, on the other hand, connotes consignment to an inferior position. When managers give employees narrow, menial tasks and expect them to do all "delegated" work exactly as they would, their action is relegation, not delegation.

Goals of delegation

Three primary goals of true delegation are to:

1. Relieve managers of some of their workload so that they have more time to think, meditate, plan, learn, and grow;
2. Move work and responsibility as far down the organizational ladder as possible, increasing efficiency; and
3. Offer all employees maximum challenge and opportunities for growth, even when formal promotions are not immediately available. This increases productivity and develops future leaders.

In harmony with these goals, proper delegation has two distinguishing characteristics:

1. Most of the delegated tasks are a meaningful part of the manager's job and not just drudgery to avoid;
2. Workers are allowed, even encouraged, to perform the delegated work in their own way, with the manager helping only when asked.

Case study: In the movie *Bullitt*, a police lieutenant is working on a case that is of intense interest to a powerful U.S. senator. The senator is not happy with the way the lieutenant is conducting the investigation, so he pressures the lieutenant's boss to force him to proceed differently. As it happens, the captain agrees with the senator but refuses to interfere, saying "It's his case, Senator."

Monitoring

Here managers can be either authoritarian (running a tight ship) or smart. They can foolishly spend much of their valuable time monitoring their operation or they can wisely delegate most of that function to employees, thus improving productivity and orderliness, fostering growth, and freeing up more time for broader, long-range tasks.

In a good work environment, the impetus for monitoring comes from below, not from above. This places a positive focus on the process. The manager trusts

group members and does not feel a need to monitor the operation closely. At the same time, employees are eager to keep managers informed because they sense that they are interested in their work and in departmental progress. They also recognize the need for management to know the general situation, to be informed of major progress or problems.

On the other hand, authoritative monitoring will yield negative results.

- Workers can't help but feel that managers don't trust them—else why would two people do one person's job? Most employees feel, correctly, that it is part of their job to monitor progress and to address problems.
- The situation is inherently inane, and perceived management inanities contribute to employee disrespect and alienation.
- Workers tend to lose interest in doing a careful job of monitoring when they see the boss repeating what they do.
- Management seldom performs lower-level tasks well. Hands-on employees, to whom such tasks are often challenging, are much more motivated and equipped to do them properly.
- Efficiency and productivity suffer, not only because of the redundancy, but because employees are forced to spend time educating the manager about the details.
- If managers get too involved with minutia, they tend to meddle in workers' jobs, and soup is not the only brew spoiled by too many cooks.

Advocating

This management task never appears in a job description, yet it is vital to enhancing the culture, environment, and performance of an R&D operation.

The world is not a fair place, and the world of work is even less fair. Why? In a free society, adults make most of their own decisions, but not in the workplace, where management and corporate rules reign supreme. Employees feel vulnerable, and "results only" oriented management practices can adversely affect their performance and well-being.

In unionized organizations, the agent or steward serves as employees' advocate (although R&D scientists are seldom part of a labor union); in nonunion companies, the Human Relations department usually fills that role. Seldom is management viewed as an advocate for workers, and rarely does management perceive itself that way. In fact, employees often consider the boss a powerful

adversary—the very reason they need an advocate! Surely productivity, not to mention loyalty and enthusiasm, suffers when workers and management consider themselves adversaries.

The manager as advocate

In a well managed, people-oriented organization, the primary advocate for each employee is the immediate supervisor. Not only is that individual in the best position to know and help workers, but she is the major beneficiary of the increased productivity, loyalty, and enthusiasm that follow. Experience has shown that if workers believe their manager is for them and wants them to succeed, and a helper and facilitator rather than an overseer; there is little they won't do for the manager. In fact, when she is under great stress or trouble, the roles become reversed and employees will rush to her aid.

Some managers believe that they should be neither advocates nor adversaries but impartial judges. However, social science professionals have shown that managers are no more rational or impartial than anyone else, that everyone labors under a cloud of personal bias. Furthermore, strict impartiality usually results in impersonal treatment, and no one likes being regarded as a "nonperson." How do managers go about becoming primary personal and organizational advocates for employees?

Personal advocacy guidelines

- Managers should get to know each person as an individual and develop a relationship based on mutual trust, respect, and caring. Then employees will feel comfortable bringing them their concerns, and the manager will be able to give employees optimum help.
- Managers need to be perceptive observers of employees, not to check up on them, but to pick up subtle signs of trouble. For example, if an ebullient person becomes very quiet on the job, and this persists for a week or two, the manager may want to say, "I don't want to be nosy, but is anything wrong? Anything I can do to help?" If the employee does not want to talk, the manager should not force the issue, but observe the situation. Showing genuine interest in individuals has a positive effect, even though they may not want to confide in their supervisor. When an employee's performance starts to decline and the manager is quite sure it is not because of any action or inaction on his part, it is best not to intrude on one's privacy; treat the employee as an adult and provide her every chance to work out the difficulties.

- If the employee's performance continues to deteriorate, there will come a time when the manager needs to meet with her and talk. But if he has built a good relationship with the employee she will most likely confide in him long before that point is reached. If the manager finds himself growing impatient with an employee during a difficulty, it's best that he wait a bit longer; it usually pays off. People appreciate a supervisor who shows patience and faith in them during times of trouble.
- When the worker does confide in the manager, he should refrain from giving advice unless asked. Any troubled individual coming to a supervisor needs, first of all, a sympathetic ear and then appropriate reassurance.
- Even when she presses him for advice, both individuals are best off if the manager simply outlines options and their advantages and disadvantages, leaving the ultimate decision to the employee.
- The manager should not try to do too much. If he senses that professional help may be appropriate, a suggestion to that effect or a referral to the company's employee assistance program may be in order.

Organizational advocacy guidelines

Not all problems are highly personal or greatly troubling. Then it is best for the manager to use his administrative ingenuity to deal directly with such problems as a temporarily stalled promotion, a continuing problem with another department, tension or a disagreement with a colleague, or resentment over an ill-defined or apparently unfair company policy. The no-advice rule softens considerably when the manager has some control over the situation. Employees do not expect management to solve all their problems, but they do expect their supervisor to try when it's important to them.

The advocating manager serves as a bridge between employees and the organization. A key girder in that bridge is "loyalty up and down." Workers need to feel that the manager is truly for them, whereas the manager's boss has to be confident that the subordinate is looking out for the company's interests as well. If the manager has a reputation as a strong advocate for employees, when irreconcilable conflicts arise (assuming no violations of ethics or the law are involved), he can come down on the side of the company without straining his relationship with workers.

One of managers' primary responsibilities is to remove impediments to employees' productivity. This can be viewed as advocacy as well, because such assistance improves workers' well-being.

Sheltering

Here is another managerial task that is missing from job descriptions, but it is very important, especially in these days of high-pressure, 60-h workweeks. What is sheltering? No matter what the weather outside, the roof, siding, and windows of a house provide a hospitable, safe environment for occupants. So, too, do managers need to create an optimum work atmosphere by sheltering hands-on workers.

Shelter them from what? Swirling about any organization are tensions, antagonisms, organizational red tape, and inanities—unpleasant and distracting. For example, perhaps the R&D vice-president, a tense, caustic individual who is uncomfortable with the deliberate pace of research, is constantly berating department managers to speed things up and increase productivity. The strong tendency in such a situation is to translate at least some of that unpleasantness and pressure down to hands-on workers—the "kick-the-dog" syndrome. With this response, not only are managers relieving some of their own frustrations and resentments, but they are convincing themselves, and trying to convince their boss, that they are team players who are bottom-line oriented. Unfortunately, such a reaction seriously damages the group's work environment and will likely reduce, not enhance, performance, especially in R&D, in which innovation and creativity require a positive atmosphere.

To avoid such debilitating problems, managers need to prevent disruption of the group's productive, relatively tranquil work environment by absorbing as much of the pressure and unpleasantness as possible. By taking most of that burden on their own shoulders, the managers protect the department from contamination by poor management practices elsewhere in the organization. This does not mean that legitimate pressures and emergencies should not filter down; employees can and will respond with vigor and enthusiasm to them, especially when the crisis is viewed as a challenge to the entire group. But no one can do their best when they are constantly pressured to hurry! hurry! hurry! Remember, "if you don't have time to do it right, where will you find the time to do it over?"

Successful sheltering is highly dependent on the level of mutual trust, respect, and confidence within the work group. When there is a strong, caring sense of family, intense sheltering is unnecessary because intrusions from the outside have minimal effect. Quality sheltering requires that managers get out of their offices and see what's going on in the department. If they have no sense of the group's day-to-day moods, detecting rising patterns

of tension or indifference becomes difficult. Also, employees are more apt to call problems to the manager's attention if they perceive her as interested, friendly, and accessible.

Five important personal qualities required for good sheltering are:

1. *Strength*. The manager needs to swim against a strong current (i.e., the system or an unreasonable, autocratic boss).
2. *Courage*. There is risk to the manager who stands up for her people against superiors or the system.
3. *Stamina*. Sheltering is a never-ending task.
4. *Ingenuity*. Deflecting a rushing stream (again, the system) usually works better than constructing a dam.
5. *Tact*. Diplomacy usually makes deflection acceptable to the system.

Managers who provide effective shelter for their employees will succeed, both with their workers and with their bosses.

Fostering Creativity

Managers contribute to creativity by:

1. Demonstrating enthusiasm and excitement for new ideas;
2. Managing with a light touch, allowing laboratory scientists the freedom to grow in their own way and at their own pace;
3. Encouraging employees to take risks and explore new territory—and being there with encouragement rather than criticism if they fail;
4. Being both flexible and secure and creating a work atmosphere with those same characteristics;
5. Being committed, not just to today's and this year's comfort and well-being, but to the long-term health of the organization and its employees; and
6. Hiring competent, innovative scientists.

Tips for encouraging creativity

1. "Two heads are better than one" is not a cliché. Ideas are often enriched through discussions with others.
2. Brain-storming sessions involving multidisciplinary groups often produce marketable ideas. The cardinal rule of brainstorming is that no expressed thought be evaluated during the session, because the threat of critique inhibits the free flow of ideas.
3. Managers should refrain from judging employees' ideas. It's best to ask workers to research their concepts with the help of their colleagues (e.g., R&D, Marketing, and Sales) and then evaluate it themselves.

4. When innovation involves replacement of old technology, management often entrusts development of the new technology to old-technology experts. At times this succeeds, but the effort often fails because these veterans have too much intellectual and emotional investment in the old way. It is usually best to assign development of new technology to competent but relevantly inexperienced scientists who will take a fresh, unencumbered approach to the problem.
5. Formal suggestion systems can be beneficial, but management must guard against calcification, by which the suggestions nourish the bureaucratic system instead of the other way around.

Motivating

When thousands of supervisors were asked to list, in descending order, what they thought motivated workers, they got it all wrong. They listed:

1. "Interesting work" as #5, but in the same questionnaire workers chose it as #1.
2. "Full appreciation for work done" as #8, whereas employees rated it #2.
3. "Feeling of being in on things" as #10 whereas workers assigned it #3.

It is clear that managers need to learn more about motivation.

Experts agree that human behavior is not random, but caused; internally motivated; and always directed toward some goal.

Strictly speaking, managers do not and cannot motivate employees. The best they can do is provide the stimuli to which workers react, driven by their own internal motivation.

Psychologist Abraham Maslow (3) hypothesized a hierarchy of needs that classifies human motivation, listed in descending priority:

1. Physiological (hunger, thirst);
2. Safety (security, stability, predictability);
3. Belongingness and social integration (companionship, being part of a group);
4. Esteem (self-respect and recognition/respect from others); and
5. Self-actualization or self-fulfillment (each person's drive to move toward being the very best of which he or she is inherently capable).

The basic needs (physiological) are most important, but once satisfied, they no longer motivate, and the next set becomes operative. Because most employees are not

starving nor threatened by anarchy, unless job security is a factor managers should be concerned with:

1. belongingness or social needs.
2. esteem, and
3. self-fulfillment.

Fostering Employee Growth

Human beings have innate pleasure in a sense of growth and improvement. — *Psychiatrist Willard Gaylin*

To foster workers' growth, managers must:

1. Understand people so that their efforts will harmonize with the realities of human nature;
2. Understand the learning process to ensure the optimal rate of growth; and
3. Apply that understanding on the job with diligence and patience.

Let's examine these three components.

Understanding people

The human characteristics most relevant to the learning/growing process are:

1. *Desire to grow.* Everyone has an inherent tendency to move toward psychological health and maturity.
2. *Personal freedom.* The more people have a say about what they do, how and when they do it, and the direction and pace of personal growth, the faster and surer they will progress.
3. *Uniqueness.* People are different from each other. Everyone is a unique individual, as varied as fingerprints. Each individual has different needs and distinct ways of satisfying those needs.

Understanding the learning process

What does an R&D manager need to know about the learning process?

- Learning can be cognitive, as in memorizing multiplication tables or reading books; or experiential, as when riding a bicycle or working effectively in groups. Most learning is a combination of the two, especially in technical organizations, in which cognitive scientific knowledge must be integrated with a wide variety of experiential skills.
- Personal growth is best achieved experientially. Carl Rogers (4) defines the elements involved:
 1. Primarily self-initiated, involving the entire person, physically, intellectually, and emotionally. A person learns best when he is ready and wants to learn;

2. Pervasive, making a difference in the attitudes and behavior of the learner;
3. Self-evaluated, in that the learner is the one who decides whether the learning experience is meeting his needs; and
4. Comprehensive, so that total (intellectual and emotional) meaning is experienced.

Application

Here are some general guidelines (keeping in mind the characteristics of a fertile work environment mentioned earlier). Leaders should:

- Manage with a light touch;
- Set a good example;
- Get to know workers as individuals;
- Involve employees as much as possible;
- Encourage risk-taking and creative thinking;
- Not underestimate employees' potential; and
- Consider overall personal growth.

Recruiting

When competent workers are hired, a manager is almost guaranteed good results. However with inadequate employees even a brilliant leader is in serious trouble. Therefore, good recruiting practices are basic to a successful R&D operation.

Effective recruiting depends first on good management of the people already on hand; the motivation, enthusiasm, and loyalty of group members will be obvious to visiting prospects.

True event. Under autocratic management, a division had 18 consecutive rejections; after changing to people-centered supervision, nine of 10 candidates accepted.

Two major steps in recruiting scientific personnel are:

1. Identifying quality candidates, and
2. Bringing them to the organization for in-depth interviews (including a seminar).

The best way to succeed with the first step is to visit universities for interviews with students. The ethical way to succeed with the second step is to have the candidate talk to as many hands-on workers as possible and to encourage interviewers to be honest and candid in answering questions about the organization. The more welcome and respected candidates feel, the better the chances they will accept an offer.

Recruiters should gather information about the candidate by talking with major advisors, other faculty members, former classmates, and formal references. The following personal characteristics are especially important:

competence, productivity, genuineness, growth potential, flexibility, open-mindedness, cooperativeness, deference, communication, self-confidence, motivation, thoughtfulness, ethics, independence, and commitment.

Conducting Formal Performance Reviews

Moral or diagnostic evaluations are always threatening.

—*Carl Rogers.*

The typical formal performance review is similar to a trip to the dentist: There is apprehension before, pain during, and a sense of relief afterward, when the session is over.

Douglas McGregor (2) explains why:

1. Evaluating an employee's performance is highly dependent on the manager's psychological makeup.
2. For various reasons (including managerial malfeasance), the appraisal often has little relation to reality.

True event. Roger, a first-line R&D supervisor, had always received above-average performance reviews. He made no waves, followed orders, did the required paperwork, and sleep-walked his way through corporate life for 10 years, totally ignoring employees' concerns and frustrations. When a new, highly competent department manager arrived, she quickly recognized Roger's incompetence and pressed for his demotion, transfer, or termination. This caused a great uproar because the "record"—a decade of innocuous, relatively positive performance appraisals by a variety of managers—painted an entirely different picture.

1. Experts agree that to a great extent, a worker's performance is a function of how he is managed.
2. Concerning criticism, the effectiveness in communication is inversely proportional to the employee's need to hear it. The more harsh the criticism, the less likely the person can/will accept it.
3. The manager may be able to convey negative judgments, but this will seriously damage the relationship.
4. Performance reviews accentuate the worker's dependence on the manager.
5. It's an open question if a troubled individual really wants to hear about his deficiencies.
6. Concerning amateur counselors (which managers are) Carl Rogers (5) says that the most they can accomplish is a temporary change, which then disappears, leaving the person more than ever convinced of his inadequacy.

There's a better, well-proven, successful approach (which assumes that all employees are performing

adequately; if that's not the case, then the manager needs to transfer or terminate unacceptable performers—see the next section).

1. Well before the actual reviews, employees are reminded that the "system" demands a formal performance appraisal and that certain rituals must, as in the past, be followed.
2. Then the manager reminds them that she has been in close contact with each of them throughout the year, and that consequently, there will be no surprises during the formal interview.
3. The manager assures everyone that their performance review will be a pleasant experience.
4. Then the manager holds formal reviews only when in a relaxed, reassuring mood.
5. When the person first comes into her office, she reiterates the first 3 points.
6. The manager emphasizes—genuinely—what a good job the employee is doing and how glad she is to have him in the department.
7. Then the manager goes into specifics concerning what she likes about the employee and his performance over the past year; he is encouraged to add accomplishments the manager has failed to mention.
8. Next, the manager reminds the employee that the system requires that she record some negatives and asks for suggestions (e.g., he often puts things off until the last minute).
9. The manager then reassures him—genuinely—concerning any weaknesses he brings up, e.g., "If you were perfect, you'd make the rest of us look bad." "Your intentions are always good, and your strengths far outweigh your weaknesses." Any additional discussion in this area should consist exclusively of the manager asking the employee how he feels about the negatives and, most important, where she—or the work situation—is deficient in helping him do his best.
10. The manager then records—honestly—the weaknesses the employee mentions, but puts them in as positive a light as possible (e.g., "Employee tends to complete some assignments at the last minute, but has a good sense of priorities and is always on schedule").
11. Then—and this is especially important—the manager asks the employee what she can do to help him improve even more. She then sits back and listens in a non defensive manner, thanking the employee—genuinely—for the candid feedback (and follows up on the suggestions).

12. The manager sums up by re-emphasizing—again, genuinely—an appreciation for the contributions to the group's accomplishments and her delight in having him as a member of the department.

In summary, criticism should be avoided here and in all management behavior, simply because it's counterproductive, and employees who feel accepted and valued by their supervisor will engage in self-criticism. This is, by far, more productive over the long term.

Transferring or Terminating Unproductive Employees

If, in spite of good management practices, a hands-on worker cannot do the job adequately, the manager is obliged to transfer the employee to a more suitable position elsewhere in the corporation. If that is not an option, then the employee should be terminated if legally possible and ethically acceptable.

Here's a recommended procedure to follow:

1. The manager should consult the Human Resources department personnel for official guidance. In fact, it is wise to work with them unofficially at a much earlier stage.
2. After ensuring that his actions have been consistent with company policy, the manager should bring the employee into his office for a private, candid, uninterrupted, and caring conversation.
3. He should begin by saying, "I'm sorry, but things are not working out and you are facing termination. You don't have to leave tomorrow, but if you were still here 6 months from now it would be a problem. Sometime between tomorrow and 6 months from now you need to find a job with a different company. I'll help you all I can, but in the end, that's your responsibility."
4. The person will almost certainly be upset and antagonistic toward the manager. At that point, he needs to remember that the employee is going through an ultratraumatic process and needs all the sympathy and support he can muster. The last thing the manager should do is try to defend his decision unless pressured by the employee, which usually does not occur.

Managers who recruit and manage well will seldom have to perform this unpleasant task.

Promoting

Proper selection of new supervisors is crucial to organizational success.

Promoting the wrong people

The most common mistakes made when choosing people for R&D management positions are:

1. Assuming the best laboratory worker will make the best supervisor (management is an entirely different world than laboratory research);
2. Choosing autocratic, results-oriented people rather than person-centered individuals; and
3. Going outside the company instead of promoting from within, which lowers employee morale and motivation.

Promoting the right people

A key element in promoting the right people is having the right people to promote; thus, recruiting the best candidates and creating a growth-fostering environment are crucial. It is also important to recognize the personal qualities (especially interpersonal orientation) needed to make a good supervisor. Managers should avoid promoting people with little talent for or interest in management. The best way to prevent this is to provide potential supervisors with temporary responsibilities and then evaluate their performance.

Organizing Project Teams

There are two common ways to organize project teams:

1. Informal (in which team members belong to scientific discipline-oriented departments with the leader's role being coordinator, not boss).
2. Formal (in which the project leader has organizational authority over team members).

In pharmaceutical R&D, it seems best to have informal project teams because:

1. Everyone needs an organizational "home" for emotional stability and security reasons, and formal project teams tend to make scientists migrant workers, e.g., when the project is completed, they are often assigned to another project with a new boss.
2. Formal project teams tend to inhibit intergroup cooperation and create unhealthy competition among teams (we should have the highest priority regarding limited joint resources and we want to make sure that our project comes out first in upper management's rating).

International R&D

Domestic R&D managers face special challenges in a multinational corporation; in general, they need to do the following:

1. Know the organizational specifics of their company's international operations;
2. Learn as much as possible about the cultural, economic, technical, and governmental differences among the various countries;
3. Establish close ties with their international R&D colleagues.

A multilingual R&D manager is especially valuable.

R&D Management and Corporate Management

R&D management needs to:

1. Understand and appreciate the views and concerns of corporate management;
2. Develop a broad vision for R&D that is harmonious with long-range corporate plans; and
3. Decide, with workers' help, what is in the best interests of the corporation.

Corporate management must learn enough about the world of R&D to:

1. Appreciate R&D's point of view;
2. Understand the R&D process so that funding is steady, not sporadic; and
3. Recognize the danger signals (confusion, aimlessness, consistently poor decisions, laboratory worker malaise) of poor R&D management to distinguish them from bad-luck cycles inherent to all R&D.

Industry and Academia

Interactions between industry and academia have mutual benefits.

Advantages for academia

1. Educational benefits:
 - Encourages the cross-fertilization of ideas;
 - Offers temporary, education-focused work in industry for faculty, undergraduates, and graduate students; and
 - Develops joint projects for increased knowledge.
2. Financial and other benefits:
 - Support for research
 - Possible employment opportunities for students after graduation
 - Consultantships for faculty
 - Rapid commercialization of academic research

Advantages for industry

1. An increased knowledge base for:
 - Cross-fertilization of ideas
 - More options for new and better products
 - More flexibility in R&D spending (academic support can be enlisted for an urgent but speculative project without making long-term internal commitments)
2. Greater professional development of employees through:
 - Teaching and lecturing opportunities in academia
 - Research sabbaticals
 - Internal short courses given by academic consultants
3. Successful recruiting of new personnel owing to:
 - More thorough evaluation of potential job candidates via summer employment of students
 - Improved corporate image among students and faculty.

LOZENGES

Robert W. Mendes

Massachusetts College of Pharmacy and Health Sciences (Retired), Dedham, Massachusetts, U.S.A.

Hridaya Bhargava

Massachusetts College of Pharmacy and Health Sciences, Boston, Massachusetts, U.S.A.

INTRODUCTION

Lozenges are solid preparations that contain one or more medicaments, usually in a flavored, sweetened base, and that are intended to dissolve or disintegrate slowly in the mouth. They can be prepared by molding (gelatin and/or fused sucrose and sorbitol base) or by compression of sugar-based tablets. Molded lozenges are sometimes referred to as pastilles, whereas compressed lozenges may be referred to as troches. They are intended to be allowed to dissolve on the back surface of the tongue to provide drug delivery locally to the mouth, tongue, throat, etc., to minimize systemic and maximize local drug activity.

The USP (1) currently recognizes Cetylpyridinium Chloride Lozenges and Nystatin Lozenges. However, more than five dozen over-the-counter (OTC) lozenge products are currently marketed (2). These contain a variety of active ingredients including antimicrobials and local anesthetics for throat pain; aromatics, herbals, zinc salts, decongestants, and cough suppressants for colds, allergy, cough, and congestion; and nicotine-like substances for smoking cessation.

HARD CANDY LOZENGES

Raw Materials

The types of raw materials used in medicated lozenges may vary according to a number of factors. Most medicated lozenges contain sugar, corn syrup, acidulant, colorant, flavor, and the medicament.

Sucrose, a disaccharide of glucose and fructose, is obtained from sugarcane or beet. The choice of beet or cane sugar is based on availability and geographical considerations. Sucrose and sucrose products are used in medicated lozenges because of their value as neutral sweeteners, their ready solubility, and their function as a “drier” to reduce the weight of the confection through crystallization. Invert sugar, derived from sucrose,

possesses the very desirable physical property of controlling the crystallization of concentrated sugar solutions and maintaining freshness of the finished product through its humectant properties.

Corn syrup is used in almost every type of confection to control sucrose and dextrose crystallization, which may lead to crumbling. Corn syrup in appropriate proportion with sucrose and dextrose allows the formation of an amorphous glass and produces a candy with the desirable appearance. The following physical properties of corn syrup are extremely important in the preparation of medicated candies: density, dextrose equivalent (DE), hygroscopicity, sugar crystallization, viscosity, freezing-point depression, and osmotic pressure.

Colorants are incorporated into medicated lozenges for appearance, product identification, and masking of physical degradation. Dyes and other organic colorants may degrade by heat or light via oxidation, hydrolysis, photooxidation, etc., and their compatibility with drug, excipients, and process conditions should be studied before selection. Suppliers of colors are excellent sources of information on current regulatory status of colorants.

Acidulants are generally added to medicated lozenges to fortify and strengthen their flavor profile. Organic acids such as citric, malic, fumaric, and tartaric acids are most commonly used. Citric acid alone or in combination with tartaric acid is the most common. Another use of acids in medicated lozenges is to alter the pH to maintain the integrity of the drug. Regular conversion corn syrup has a pH of 5.0–6.0. Addition of a weak organic acid to improve flavor lowers it to 2.5–3.0, a pH at which some medicaments exhibit maximum stability (3). If necessary, some drugs can be stabilized by adjusting the pH to 7.0–8.0 with a suitable weak base such as calcium carbonate. Some research has shown that excessive use of acidic lozenges could have the potential to enhance existing dental erosion (4), and that low pH (2.6–3.7) leads to dissolution of calcium and phosphorous from hydroxyapatite (5). Others have shown that excessive use of citric and tartaric acids may effect bioavailability of zinc in zinc lozenges (6, 7). Another report indicated that

the activity of cetylpyridinium chloride in candy-base lozenges is influenced by pH, with >5.5 being most desirable (8).

Acceptable taste is necessary to ensure patient acceptability, and this can be the determining factor between commercial success and failure of an OTC product. Flavors used in medicated lozenges must be compatible with the drug and excipients and capable of withstanding the rigors of the manufacturing conditions. Flavors consist of numerous chemicals that may interact with excipients or medicaments and that degrade by heat and light. Aldehydes, ketones, and esters may react with drugs. A classic example of flavor-drug interaction is that of a primary amine drug (benzocaine, phenylpropanolamine) with aldehyde-containing flavor components like cherry, banana, etc., resulting in the formation of a Schiff base, drug decomposition, and loss of efficacy. Adjustment of lozenge base pH to accentuate certain flavors (e.g., citrus) may also result in incompatibility with some medicaments (e.g., benzocaine).

The last major ingredient in lozenges is salvage obtained from lozenge batches rejected because of imperfect shape or size, presence of air bubbles, or unacceptable drug concentration. Salvage, if properly heated, can be reused in finished products without altering color, texture, lozenge base composition, or drug concentration (9). Before any salvage can be used as part of a medicated lozenge base, it should be adjusted to a pH of 4.5–7.5 to prevent excessive and uncontrolled formation of reducing sugars, and the stability of the drug at cooking cycles should be determined.

Processing Methods

There are three types of candy-base cookers: fire cookers, high-speed atmospheric cookers, and vacuum cookers. Vacuum cooking is the process of choice for manufacturing hard candy lozenges. It is based on the principle that water boils at a lower temperature under vacuum, and can thus be removed. Sugar solutions and corn syrup are boiled at 125–132°C, vacuum is applied, and, due to the heat of the batch, additional water is boiled off without further heating. The resulting vapor is condensed and removed by the cooling water of the vacuum pump (3).

The continuous batch process cooker installation consists of an automatic sugar dissolver, a sugar solution and corn syrup storage unit, metering pumps, precookers and a holding tank, a vacuum pump, and a collection kettle (10). Precookers are standard steam-jacketed kettles equipped with an additional heat exchanger to provide better circulation in addition to more exchange surfaces. Each component (water, sugar, corn syrup, and

salvage) is added by pumps and metering devices controlled by one gearing system, in order to bring the finished precooked syrup to the desired temperature (110–120°C) in 1 min or less (3). The short dwell time significantly reduces the Browning reaction and the amount (1–2%) of invert sugar developed (11). Cooking machines consist of a heating coil, intermediate chamber, vacuum chamber, flow metering valve, turning device that charges the receiving kettle, receiving kettle, kettle turning device, and rotary vacuum. In the standard procedure, a precooked sugar–corn syrup solution at 110–120°C is passed through a chrome–nickel steel cooking coil housed in a steam dome at a temperature of 135–150°C. The coil leads to an intermediate chamber that is vented to the atmosphere. From the intermediate chamber, the syrup is sprayed into the vacuum chamber, which is regulated by a vacuum-actuated metering valve. This affects reevaporation of the sugar mass (12), further increasing the content of dry substance. An adjustable timing device charges the receiving kettle by opening an air valve the moment the batch is cooked. The filled receiving kettle drops from the vacuum hood and is held in front of the cooker by a spring-activated timing device; it is replaced by an empty one (3). The kettle is charged by the syrup pump, resulting in uniform weight of all batches. By selecting an appropriate model, more than 3000 kg of candy can be produced per hour.

Replacement of the collection kettle by a continuously moving stainless steel belt to carry the candy base away from the cooker at a predetermined rate in an unbroken stream has resulted in the continuous process cooker, which has some advantages and some limitations. Its advantages are high-speed production, improved organoleptic characteristics, extended shelf life for physical properties, and cost effectiveness. The disadvantages are reduced controls, the addition of flavor at very high temperature, and increased possibility of nonuniform candy-base production. Preparation of candy base from gear metering of sugar solution and corn syrup to vacuum drying is identical to the batch process described above. However, candy base is continuously drawn off in a thin ribbon. As it leaves the cooker the flavor, preheated to 50–60°C, is injected. The flavored candy mass is dropped onto a variable-speed rotary cone head where it is mixed. Medicament as a solution or dispersion, preheated to 110–120°C, can be metered into the candy mass through dosing pumps. The candy mass then slides down the delivery chute onto the stainless-steel belt where it is mixed and sized by plows and rollers. The temperature of the conveyor belt is controlled by a spray of heated water that can be adjusted as necessary. The acidulant may be deposited onto the candy mass via a vibratory dosing

auger (9); the subsequent steps are identical to those of the batch process.

Candy-Base Manufacturing

The first step in the manufacture of medicated lozenges is the preparation of candy base, followed by the addition of medicament, flavor, acidulants, colors, etc., and finally by lozenge formation. Irrespective of process, the manufacture of medicated lozenges involves the cooking of candy base, mixing, batch forming, "rope" sizing, adjustment of weight, lozenge formation, cooling, and storage of lozenges.

Candy base is prepared from liquid sugar (67% sugar) and corn syrup (liquid glucose 43°Bé, 80% solids) in a ratio of about 60:40. Precooking is initiated under vacuum at controlled temperature. The precooked solution is transferred into the steam-heated coil, where it is boiled and from which it is moved to the intermediate chamber where final mixture is produced (3). The final moisture content of candy base should be about 1%, its temperature about 135°C, and its consistency plastic-like. The candy base is transferred into a kettle mounted on a suitable scale and, if necessary, batch weight is adjusted.

Heat-stable colors are added at this point as cubes or paste. The colored candy base is transferred to a cold stainless-steel cooling plate for the mixing operation. Mixing can be manual or mechanical, using a series of plows and rollers, or a mixer consisting of two arms, a plunger, and a slowly rotating table top.

The temperature of the mixing table is maintained at 40–50°C. Flavor, medicament, acidulant, and ground salvage are added to the colored candy mass when mixing is initiated. After completion, the medicated candy base is transferred to a warm slab and allowed to equilibrate to a uniform temperature.

The mass is cut into workable portions, properly tempered, and placed into batch-forming (holding) machines. For candy formers requiring a flat sheet, heated tables are used. For candies requiring cylindrical pieces to be fed into the batch formers, batch rollers are used. A plastic-like mass is formed into a sugar cone and transferred at a predetermined rate to the sizing roller. The operation of the batch former is synchronized with the rope sizer (12). In order to maintain a temperature at which the outer shell of the candy would not crack, the batch formers are kept at 80–90°C (3).

The height to which the batch formers are adjusted and the amount of material in them dictates the delivery rate of the candy flowing as a rope from the batch former to the sizing rollers. The sizers consist of sets of successively smaller forming rolls. The thickness of the rope is

determined by the diameter of the sizing rollers and governs the weight and size of the candy. The sizers are generally heated to maintain temperatures of 50–60°C, preventing the candy from cracking by rapid cooling (12).

For the formation of the final lozenge, the candy rope is discharged into a forming machine. The formed lozenges are then fed onto the distribution belt, which provides intensive cooling and shaking to prevent deformation of the still plastic lozenge (12).

The formed candy must be cooled as quickly as possible to prevent loss of shape. The candy is usually cooled on a conveyor belt made of chain or canvas. Multibelt coolers are designed in such a way that the first narrow belt (15–20 cm wide) runs as rapidly as the candy-forming machine. At the end of the first belt, a breaker separates the candy and distributes the lozenges uniformly across a wider, slower-moving second belt. The third belt is still wider and travels even more slowly, allowing enough time to cool the lozenge to the desired temperature (below 35°C) (3).

In the sizing operation, the medicated lozenges are collected as they leave the cooling belt and transferred to a series of counterrotating rollers separated via caliper adjustment (12). The sizing operation removes all oversized and undersized lozenges, ensuring uniformity.

The properly sized lozenges are collected and stored in a climate-controlled room at 15–20°C and a relative humidity of 25–35% until the product is cleared by the quality control unit for packaging.

Recent technological advances in lozenge manufacture include a patent (13) that teaches a continuous process for producing dextromethorphan lozenges. A new lozenge cutter apparatus consisting of a drum with an array of cutter elements is described in a 1997 patent (14). A distributing device for feeding lozenges (or other flat products) via a feed conveyor to a "user" machine, such as a packager, is described in a 1993 patent (15).

COMPRESSED TABLET LOZENGES

Commercially, the preparation of lozenges by tablet compression is less important than hard-candy manufacturing techniques. Essentially, lozenge tablets differ from conventional tablets only in their organoleptic and nondisintegrating properties and slower dissolution rate. The associated attributes of pleasant taste with or without matching color, smoothness, and mouthfeel during prolonged dissolution on the tongue, and the physical consideration of holding the tablet in the mouth while swallowing its dissolved components, present unusual

formulation requirements compared to those of tablets intended for swallowing or chewing. The commonly used drugs mentioned previously tend to be bitter, unpleasant tasting compounds. The desire to release these agents slowly in the mouth, in constant contact with the tongue, demands a formulation approach unlike that found in any other dosage form.

Processing and Excipients

Any of the common tablet-processing methods, such as wet granulation, dry granulation, or direct compaction, may be utilized in the production of lozenge tablets. However, because the tablets should dissolve very slowly without disintegration, wet granulation is preferable because it generally provides better control. Through the judicious use of wet binders that retard dissolution, it should be possible to design a formulation having the appropriate dissolution rate.

Formulating for slow dissolution, plus smoothness and good mouthfeel, requires careful excipient selection and appropriate process development to ensure that the controlling variables are dealt with correctly. Several important aspects of lozenge tablet manufacture are critical to all of the desired performance attributes of the finished product. These include assurance of necessary particle size and distribution, maintenance of correct moisture content, and achievement of proper tablet hardness. Process development and scale-up considerations must be thoroughly explored to ensure the establishment of proper specifications for these parameters. As always when the process involves wet granulation, the extent of wetting and the rate and extent of drying must be defined. Overwetting almost certainly produces harder granules that may have poor compressional characteristics, resulting in softer and more friable tablets unacceptable for lozenge application. Because of the lesser degree of particle deformation, such granulations produce tablets having a gritty mouthfeel. Overwetting also leads to longer drying times in order to achieve the desired moisture level or, to a higher moisture level due to failure to compensate through adjustment of the drying cycle.

Lozenge tablets are generally formulated as relatively large-diameter (>12.5 mm), flat-faced (beveled edge), heavy (>700 mg) tablets with high hardness (>15 kp). These physical attributes lead to ease of use in the mouth and contribute to the desired slow dissolution. The formulation factors primarily responsible for controlling dissolution, hardness, and mouthfeel are the presence of a high strength, dissolution-retarding binder and the absence of a disintegrant. Several commonly employed binders (16–18) meet these criteria and provide the

added benefit of delivering a demulcent-like action in the throat.

Gelatin (in the form of a warm 10% aqueous solution) and acacia gum (in the form of an aqueous mucilage) in wet granulation form very hard tablets with slow dissolution. Guar gum, used as an aqueous thixotropic mucilage, exhibits behavior similar to that of acacia gum.

The sugar bases frequently associated with lozenge tablets are sucrose or compressible sugar, dextrose, mannitol, and sorbitol, which are available in special tableting grades from a variety of excipient manufacturers. Generally intended for direct compaction applications, they may also be utilized with the above binders in wet-granulation systems. Lactose, because of its extremely low sweetness (15% of sucrose), is limited for use in lozenges because it would require the addition of an artificial sweetener of sufficient potency to overcome its blandness. Xylitol is relatively sweet and has an advantage in lozenge formulation with respect to its lack of caries production.

Artificial sweeteners are of significant importance to lozenge tablet formulations. As noted above, some sugars may not be sweet enough to mask the bitterness or sourness of many drugs. Presently, there is considerable regulatory disagreement worldwide concerning these materials; some are approved for use in certain countries but not others. Aspartame, asulfame-K, cyclamate, saccharin, and sucralose appear to be technically usable, but their selection requires care from the regulatory perspective. All have potency (sweetness) levels orders of magnitude higher than that of sucrose, permitting the use of very low concentrations (less than 1%) to cover most bitter drugs. Semisynthetic sweeteners, derived from glycyrrhiza, have enjoyed some degree of popularity over the years. They are much sweeter than sucrose, but less sweet than saccharin. It is strongly recommended that the formulator validate the current regulatory acceptance of the intended sweetener prior to its use for a particular product and market country. In addition, a recent report suggests that the common lubricant, magnesium stearate, reduced the effectiveness of cetylpyridinium chloride in compressed tablet lozenges, and that the concentration of this ingredient in such a formulation should be maintained at not more than 0.3% (19).

QUALITY CONTROL

Lozenges require the same quality assurance and control measures as any pharmaceutical dosage form. Because of their unique composition, however, certain additional methods are necessary.

In-Process Testing

In addition to all of the common in-process tests used for all dosage forms, certain specialized procedures are necessary for hard candy lozenges. These include checking the corn syrup and sugar delivery gears, temperature, steam pressure, and the cooking speed of precooker and cooker; analysis of the candy base and its moisture content, and determination of the sugar-to-corn syrup ratio using the dextrose equivalent method, percent-reducing sugar (by reacting candy with copper sulfate and alkaline cupric tartrate and titrating with dextrose solution), pH, cooked candy batch weight, lozenge weight, and lozenge size. The usual in-process tests for compressed tablets apply to lozenge tablets, including particle-size distribution, moisture content, flow, blend uniformity, tablet weight and thickness control, hardness, etc.

Batch-Release Testing

In addition to the usual quality control procedures and the above in-process tests, batch-release testing includes dosage uniformity and a test for grittiness, performed by partially dissolving lozenges under running tap water until one-third to one-half has been removed. No grittiness must be felt when rubbed between thumb and forefinger.

Test procedures that are ordinarily applied to compressed tablets are also employed for lozenge tablets. However, because the lozenge is intended to dissolve slowly in the mouth, typical disintegration and dissolution testing is inappropriate. Lozenges should be nondisintegrating; therefore, there is no need for disintegration testing. Dissolution specifications should be developed on the basis of a minimum and maximum time to physically dissolve, rather than on the basis of minimum percent drug released in the maximum time interval. As with hard candy lozenges, microbial testing may be appropriate, especially when wet granulation has been used in processing the materials and high concentrations of carbohydrates are present.

Stability

For both hard candy lozenges and compressed tablet lozenges, stability considerations extend to areas not usually of concern with other types of tablets. These products should not only conform to chemical and physical specifications, but should also exhibit satisfactory stability of organoleptic attributes. Because lozenges are flavored, flavor stability is important. There is, however, no objective method for measuring flavor stability in a finished dosage form, although GC may be used for chemical analysis of flavor compounds. Even subjective methods such as tasting are difficult because formal taste

panels are needed to acquire reliable data. Subtle changes in flavor with time, although not affecting product performance, may have a significant impact on product market acceptability. This could also be true of minor changes (increase or decrease) in tablet hardness, which could affect dissolution time and therefore acceptability.

PACKAGING

Medicated lozenges, especially those of hard candy base composition, are hygroscopic because of their unique ingredients. In order to be competitive in the marketplace, they need a shelf life longer than 3 years. For these reasons, they are usually packaged individually wrapped in polymeric moisture-barrier material. The wrapped lozenges are placed in a tight or moisture-resistant glass, polyvinyl chloride, or metal container that is overwrapped with cellophane or aluminum foil. This complex, multiple packaging is intended to provide the maximum possible protection from moisture in order to ensure the longest possible shelf life for the product.

SUMMARY

Lozenges are medicated confections designed to locally deliver drug to the mouth and throat. Very widely sold as OTC products, there are also prescription products marketed in the lozenge dosage form. Lozenges are used to deliver local anesthetics, cold and allergy treatments, antimicrobial drugs, antismoking drugs, and anticarcinogenic drugs. They are usually produced in the form of cooked, hard candies based on sugar and corn syrup or sorbitol. They are totally different from any other pharmaceutical dosage form in terms of ingredients and method of manufacture and, therefore, require specialized facilities. Compressed tablet lozenges differ from conventional tablets by requiring materials and methods that provide slow dissolution and drug release.

For these and other reasons, lozenges are produced by few pharmaceutical manufacturers, and represent a very small percentage of total pharmaceutical sales. No significant growth can be currently anticipated in these areas.

LIQUID ORAL PREPARATIONS

Jagdish Parasrampuria

Galderma R&D, Cranbury, New Jersey, U.S.A.

INTRODUCTION

Liquid oral preparations are composed of many types of formulations, both aqueous and nonaqueous, including solutions, suspensions, and emulsions. Oral solutions are homogeneous mixtures of one or more solutes dissolved in a suitable solvent or mixture of mutually miscible solvents. In pharmaceutical terms, solutions are defined as "liquid preparations that contain one or more soluble chemical substances, usually dissolved in water and they do not, by reasons of their ingredients, method of preparation, or use, fall into another group of products" (1). Solutions are classified on the basis of physical properties, method of preparation, use, and type of ingredients (Table 1) (2). The distinction among different types of solutions is not always clear because of overlap in definitions. Therefore, in some instances, definitions are not important for commercial products.

APPLICATIONS

Liquid oral preparations are useful for a number of reasons. Patient compliance is often a problem with oral solid dosage forms, especially with young children and the elderly. This refusal to accept medication stems from the difficulties experienced by these age groups in swallowing tablets or capsules. Such difficulties can be overcome by administering the active compound in a palatable liquid form. An oral liquid can be readily administered to children and the elderly who are unable to swallow. Because solutions are homogeneous mixtures, the medication is uniformly distributed throughout the preparation. The dose can be easily adjusted as fractional doses by dilution to meet the needs of the patients. Extracts eliminate the need to isolate the drug in pure form, allowing several ingredients to be administered from a single source (e.g., pancreatic extract) and permit the preliminary study of drugs from natural sources. Some deliquescent and hygroscopic powders are more easily dispensed as liquids. Some drugs that are not tolerated in a concentrated form may be less irritating if dissolved in soothing liquid (3). Occasionally, solutions of drugs such

as potassium chloride are used to minimize adverse effects in the gastrointestinal tract. Because drugs are absorbed in their dissolved state, the rate of absorption of oral dosage forms usually decreases in the following order: aqueous solution > aqueous suspension > tablets or capsules. A drug administered in solution is immediately available for absorption from the gastrointestinal tract and is more rapidly and efficiently absorbed than the same amount of drug administered in a tablet or capsule.

LIMITATIONS

Drug substances in general are less stable in liquid media than in the solid dosage form. Special techniques are required to solubilize poorly soluble drugs. Masking the taste of inherently very bitter drugs is sometimes difficult. Extremely potent drugs with a low therapeutic index cannot be given in an oral liquid dosage form because dosage measurement errors could be made by the patients. As with other oral dosage forms, liquid oral preparations cannot be administered to the unconscious patient.

DESIGN AND FORMULATION

The design of liquid oral solutions involves the combination of ingredients with medicinal agents to enhance the acceptability or effectiveness of the product. The formulation of pharmaceutical liquids requires several considerations: concentration of the drug; solubility of the drug; selection of the liquid vehicle; physical and chemical stability; preservation of the preparation; and appropriate excipients such as buffers, solubilizers, sweetening agents, viscosity-controlling agents, colors, and flavors.

Pharmacists can handle liquid preparations in three ways (4): They may dispense the product in its original container; they may buy the product in bulk and repackage it at the time of dispensation; or they may compound a solution. Compounding may involve nothing more than mixing two marketed products in the manner indicated on the prescription or may require the incorporation of an active ingredient in a logical and pharmaceutically

Table 1 Classification of oral solutions

Type	Description
Syrup	Solutions containing high concentrations of sucrose or other sugars
Elixir	Sweetened solutions containing alcohol as a cosolvent
Spirit	Hydroalcoholic solutions of aromatic or volatile substances
Aromatic Water	Aqueous solutions of aromatic or volatile substances
Tincture	Hydroalcoholic solutions prepared from vegetable materials or chemical substances by dissolution or extraction
Fluid extract	Concentrated alcoholic solutions of animal or vegetable drugs obtained by removal of active constituent by extraction (maceration, percolation)

(From Ref. 2.)

acceptable manner into the aqueous or nonaqueous solvents forming the bulk of the product. Most prescriptions today are dispensed in their original containers. In these cases, the pharmacist depends on the manufacturer to provide a product that is effective, pharmaceutically acceptable, and stable when stored under recommended conditions. Most drug manufacturers attempt to guarantee efficacy by evaluating their products in a scientifically acceptable manner. However, in some instances, such efficacy is relative. For example, cough mixtures marketed by two different manufacturers may contain active ingredients of the same therapeutic class and concentration. It therefore becomes difficult to assess the relative merit of the two products. In such cases, the commercial advantages gained by one over another may be based on other product characteristics. Thus, color, odor, taste, pourability, and homogeneity are important pharmaceutical properties. Hence, the successful design and formulation of liquids, as well as other dosage forms, require both scientific and pharmaceutical acuity (5).

Solubility

Solubility is of prime importance in developing liquid oral solutions. The drug and other dissolved substances should remain solubilized throughout the shelf life of the product. Therefore, the drugs are present in solution at unsaturated concentrations; otherwise, the drug may crystallize as a result of changes in temperature or by “seeding” from other ingredients or particulate matter present. The taste of organic drugs has been shown to be a direct function of aqueous solubility (6). For example, increasing the chain length of clindamycin esters (thus reducing aqueous solubility) dramatically improves the taste (7).

It is also important to determine solubility at refrigeration temperature (2–8°C) to establish the usable concentration in the range of 2–25°C without the risk of

saturation and crystal growth. This procedure is necessary to cover the wide range of temperature conditions to which the product may be exposed during the normal distribution process. If the exact solubility has not been determined, general expressions of relative solubility may be used. These terms are defined in the *United States Pharmacopeia* (USP) and are listed in Table 2 (8).

The solubility of the drug substance is attributable in large part to the polarity of the solvent, often expressed in terms of dipole moment, which is related to the dielectric constant. Solvents with high dielectric constants dissolve ionic compounds (polar drugs) readily by virtue of ion–dipole interactions, whereas solvents with low dielectric constants dissolve hydrophobic substances (nonpolar drugs) as a result of dipole or induced dipole interactions (Van der Waals, London, or Debye forces). This principle is illustrated in Fig. 1 (9). The former is classified as polar solvents, with examples such as water and glycerin; the latter are nonpolar solvents, with example such as oils. Solvents with intermediate dielectric constants are classified as semipolar. The dielectric constants of some solvents are shown in Table 3 (8).

Table 2 USP terms of solubility

Terms	Part of solvent required to dissolve 1 part of solute
Very soluble	<1
Freely soluble	1–10
Soluble	10–30
Sparingly soluble	30–100
Slightly soluble	100–1000
Very slightly soluble	1000–10,000
Practically insoluble, or insoluble	>10,000

(From Ref. 2.)

Liquid Oral Preparations

Fig. 1 Influence of solvent polarity on the solubility of drugs: A) Polar drug; B) semipolar drug; C) nonpolar drug. (From Ref. 9.)

A substance often exists in more than one crystalline form, such as chloramphenicol, dehydroepiandrosterone (DHEA), progesterone, sulfathiazole, cortisone or prednisolone, to name a few. Polymorphic transformations are structural differences resulting from different arrangements of molecules in the solid state.

Solubilization Techniques

Sometimes the desired drug concentration in a liquid dosage form cannot be reached because of the drug's low water solubility. Solubilization is the process by which the apparent solubility of a poorly water-soluble substance is increased. Solubilization techniques include addition of a cosolvent, salt formation, prodrug design, complexation,

Table 3 Dielectric constants of solvents at 25°C

Solvent	Dielectric constant
Water	78.5
Glycerin	40.1
Ethanol	24.3
<i>n</i> -Propanol	20.1
Benzyl alcohol	13.1
Polyethylene glycol 400	12.5
Cottonseed oil	3.0

(Modified from Ref. 8.)

Table 4 Comparison of drug solubilization techniques

Method	Approximate range of solubility increase	Reference
Cosolvency	1–1000×	(10)
Salt formation	1–1000×	(11)
Prodrug formation	1–1000×	(12)
Complexation	1–100×	(13)
Micellization	1–50×	(14)

(From Ref. 9.)

particle size reduction, and the use of surface-active agents (micellization). Table 4 shows a comparison of the magnitude of increase in solubility obtained in general with various solubilization techniques (9).

Cosolvency

Cosolvents are defined as water-miscible organic solvents that are used in liquid drug formulations to increase the solubility of poorly water-soluble substances. Cosolvency, then, refers to the technique of using cosolvents. The need to use cosolvents in the formulation of new drugs as solutions remains high, especially with the increasing structural complexity of new therapeutic agents. The importance of using cosolvents in the formulation of a peptide drug has been reported (14).

Cosolvency is highly effective in increasing drug solubility. Advantages include not only the large increases in drug solubility but also simplicity. In the past, ethanol was the most commonly used solvent in oral preparations because of its excellent solvent properties for many nonpolar drugs as well as its favorable taste. Its use is often undesirable, however, in preparations intended for pediatric patients. Ethanol may also accentuate the saline taste of ionic salutes (15). Sorbitol, glycerin, propylene glycol, and several polyethylene glycol polymers are cosolvents that are both useful and acceptable in the formulation of oral liquids. For example, Fig. 2 shows solubilization curves of alprazolam in cosolvent–water systems (16). Cosolvents are used not only to effect solubility of the drug but also to improve the solubility of volatile constituents used to impart a desirable flavor and odor to the product. The primary limitation of cosolvency is the toxicity of most water-miscible solvents that have a high potential for increasing drug solubility. The toxicological properties of a solvent that may limit or eliminate its use in drug formulations include its general toxicity, target organ toxicity, or tissue irritation. Even if found to be relatively nontoxic, a cosolvent can rarely be administered as a neat or 100%

Fig. 2 Solubilization of alprazolam by ethanol (□), propylene glycol (○), and glycerin (Δ). (From Ref. 16.)

solvent because of its poor taste or objectionable odor. Although a cosolvent may increase the solubility of the drug, it may also affect the solubility of other polar or ionic components of the formulation such as buffer materials.

Early formulation work using cosolvency involved an empirical approach for choosing the type and amount of cosolvent for a liquid vehicle. An improvement in the purely empirical approach was the introduction of alligation methods that could be used to reformulate vehicles based on experimental formulation or solubility

data. Moore (17) reported a method using approximate dielectric constants of the pure and mixed solvents. The basic assumption is that all vehicles with the same dielectric constant solubilize a given drug to the same extent. However, the dielectric constant alone is a poor predictor of the degree of drug solubility. Rubino (9) has described various mechanisms and equations that were derived with the objective of establishing a basic understanding of and developing a mathematical approach to interpreting and predicting drug solubility behavior.

Salt formation

Many poorly soluble drugs can be solubilized in salt form (18). The compound (α -(2-Piperidyl) β -3,6-bis(trifluoromethyl)-9-Phenanthrenemethanol, an antimalarial agent, and its hydrochloride salt are both only slightly soluble in water. However, its lactate salt is approximately 200 times more soluble than the hydrochloride. This enhanced aqueous solubility is attributed in part to the decrease in crystal lattice energy, as indicated by a reduction in the melting point. If a particular salt form cannot be isolated because of its very highly solubility, the same end result (i.e., desired aqueous solubility) can be achieved by in situ salt formation. This is accomplished by using an appropriate acid or base to adjust the pH level while formulating the drug product solution.

Prodrug method

The solubility characteristics of a drug can be altered by chemical modification; this is referred to as the "prodrug" approach. The term was first used by Albert (19) for a compound that undergoes biotransformation before eliciting a pharmacological response. This method has been successful in the case of corticosteroids. The solubility of betamethasone in water, for example, is 5.8 mg/100 ml at 25°C. The solubility of its disodium phosphate ester is more than 10 g/100 ml, an increase in solubility greater than 1500-fold. Although methods such as salt and prodrug formation can result in high increases in solubility, they require synthesis of essentially new drug entities as well as additional animal studies to confirm their efficacy and safety. Thus, an undertaking of this magnitude can be justified only if no other reasonable approach is available.

Complexation

Complexation is another means of improving the aqueous solubility of insoluble compounds; it is described by Eq. 1:

where $[D]_s$ = concentration of drug in solution; $[L]_s$ = concentration of ligand in solution; and

$[D_n:L_m]_s$ = concentration of the drug-ligand complex solution.

A complex is an entity formed when two molecules, such as a drug and a solubilizing agent (ligand), are bound by weak forces (e.g., dipole–dipole interaction or hydrogen bonding). For complex formation to occur, drug and ligand molecules must be able to donate or accept a pair of electrons.

Complexation has several advantages, such as the reversibility of the interactions. Dissociation of the complex to the individual reactants occurs rapidly and spontaneously on dilution. Consequently, the biological effects of complexes can be predicted on the basis of knowledge of the pharmacological properties of each of the reactants. Another advantage is the predictability and physical stability of the systems. Because complex formation involves equilibrium attainment, once the necessary data defining the system parameters such as stability constants and solubility properties of the complexes have been gathered, the behavior of the system is totally reproducible and predictable. This is in contrast to the polymorphs and other crystal modifications, which can be thermodynamically unstable; they may undergo time-dependent changes, that may lead to changes in solubility behavior.

The disadvantage of complexation is the presence of the ligand in molar ratios equivalent to and often higher than those of the drug. However, its sensory or pharmacological effects may be unacceptable. The formulator must also take into account detrimental interactions of the ligand with the excipients. Furthermore, the apparent solubility increase realized by complexation compared with other techniques is usually less by an order of magnitude.

Micellization

Micellization has been defined by McBain as the spontaneous passage of poorly water-soluble solute molecules into an aqueous solution of a soap or a detergent in which a thermodynamically stable solution is formed (20). The mechanism for this phenomenon has been studied extensively and involves the property of surface-active agents forming colloidal aggregates known as micelles. When surfactants are added to a liquid at low concentrations, they tend to orient at the air–liquid interface. As additional surfactants are added, the interface becomes fully occupied, and the excess molecules are forced into the bulk of the liquid. At still higher concentrations, the molecules of surfactant in the bulk of the liquid begin to form oriented aggregates or micelles; this change in orientation occurs rather abruptly, and the concentration of surfactant in which it occurs is known as

the critical micelle concentration (CMC). Solubilization is thought to take place by virtue of the solute entrapped in or absorbed onto the micelle. Thus, the ability of surfactant solutions to dissolve or solubilize water-insoluble materials starts at the critical micelle concentration and increases with the concentration of the micelles.

It has been observed that lyophilic surface–active agents with hydrophilic–lipophilic balance (HLB) values above 15 are the best solubilizing agents. The commonly used solubilizing agents in pharmaceutical systems include polyoxyethylene sorbiton fatty acid esters (Tween series), polyoxyethylene monoalkyl ethers (BRIJ and MYRJ series), and sorbiton fatty acid esters (Span series). The choice of solubilizing agents is based on phase-solubility studies in which the solubility of the drug is determined as a function of surfactant concentration; several surfactants are included in these studies. The appropriate surfactant can then be selected on the basis of its efficacy as a solubilizer and its effect on other product characteristics and formulation adjuvants.

STABILITY

Drug substances in general are less stable in liquid media than in the solid dosage form. As a class of formulations, oral liquids are more complex in their composition than are parenterals, and more interactions can occur that might affect the stability of the product. Not only is it necessary to consider the solution stability of the drug, but also the effects on stability caused by excipients such as colorants, flavors, preservatives, solubilizers, thickening agents, and sweetening agents.

Chemical Stability

The techniques for predicting the chemical stability of homogeneous drug systems are well-defined (21, 22). The formulation chemist should consider both the pH-solubility profile and pH-stability profile to select the optimum pH for formulating the liquid oral dosage form. For example, Figs. 3 and 4 show that pH-stability and pH-solubility profiles (23, 24), respectively, for acetazolamide are approximately 4, which is the pH of optimum stability. However, the solubility above pH 7 is much higher because of sodium salt formation.

Physical Stability

Physical instability of liquid formulations involves the formation of precipitates, less soluble polymorphs,

Fig. 3 pH-Stability profile of acetazolamide. (From Ref. 23.)

adsorption of the drug substances onto container surfaces, microbial growth, and product appearance (25). The acceptability of the product is a subjective evaluation and includes properties such as color, odor, taste, and clarity. Dye stability depends on the excipients used in the formulation. For example, FD&C Blue No. 2 has been

Fig. 4 pH-Solubility profile of acetazolamide. (From Ref. 24.)

found to fade more rapidly in the presence of several sugars (sorbitol, mannitol, dextrose, sucrose, lactose). In addition, trace amounts of impurities and nonionic surfactants such as pluronic F-68 contribute to the fading (26, 27).

Preservatives have been shown to bind to macromolecules (28); for example, the binding of methyl *p*-Hydroxybenzoate to nylon was found to be dependent on the size of the nylon membrane and the concentration of free methylparaben. The complexation of methyl *p*-Hydroxybenzoate with Tween 80 depends on the amount of free methylparaben and the concentration of Tween 80. Similar results have been reported for propyl *p*-Hydroxybenzoate.

COMPONENTS AND ADDITIVES

Sweetening Agents

Sweeteners are indispensable for liquid oral dosage forms. They are used to mask bitter or unacceptable tastes of constituents. Sweetening agents constitute a major portion of the solid content in most liquid oral dosage forms. The most commonly used sweeteners include sucrose, sorbitol, mannitol, liquid glucose, honey molasses, saccharin, and aspartame (Table 5). The types and concentrations of sweeteners for common prescription liquid medications are reported by Hill et al. (29).

Sucrose is the most widely used sweetener with a long history of use. It is a white crystalline powder, soluble in water and alcohol. It inhibits the growth of micro-organisms in solution at a sucrose concentration above 65 wt% by reducing the water-activity coefficient. Official Simple Syrup is an 85% w/v solution of sucrose in water. During the preparation of sucrose solution, care should be taken to avoid charring and caramalization caused by heat. Sucrose is chemically and physically stable in the pH range of 4.0–8.0. It is frequently used in conjunction with sorbitol, glycerin, and other polyols, which reduce its tendency to crystallize. One of the manifestations of the sucrose crystallization is “cap-locking” which occurs when sucrose crystallizes on the threads of the bottle cap and interferes with opening.

Liquid glucose is an extremely viscid substance that imparts both body and sweetness to liquid formulations. It is obtained by the incomplete hydrolysis of starch and consists chiefly of dextrose, dextrans, maltose, and water. It imparts a characteristic odor and flavor to the formulation in a manner similar to that of honey and molasses but to a lesser degree. Although liquid glucose is

Table 5 Sweetening agents

Sweetener	Sweetening power	Chemical structure	Comment
Sucrose	≈ 1		Most commonly used
Saccharin	≈ 500		Unpleasant aftertaste
Sodium cyclamate	≈ 30		Banned
Aspartame	≈ 200		Not very stable in solution

not a pure chemical entity, its method of manufacture can be well-controlled, and batch-to-batch variability is usually not a significant problem. The same is not true of honey and molasses, in which the quality depends on the sources, the time of the year they are produced, and natural factors that cannot be controlled.

Saccharin is a synthetic sweetening agent. It has approximately 500 times the sweetening power of sucrose, depending to some extent on the strength of the solution. The relative sweetening power of sucrose, depending to some extent on the strength of the solution. The relative sweetening power is greatest in dilute solution. Saccharin is a sucrose substitute for diabetics, the obese, and others who do not wish to ingest sucrose. It has no food value and is commonly used in the form of its sodium salt, which is more palatable than saccharin and comparatively free of unpleasant aftertaste. Sodium cyclamate is another synthetic sweetening agent that is approximately 30 times as sweet as sugar. However, its use as an artificial sweetener is no longer permitted in most countries because of the possible toxicity of its metabolite cyclohexylamine.

Aspartame, *N*-L- α -Aspartyl-L-Phenylalanine methyl ester, is 200 times sweeter than sucrose and, unlike saccharin, has no aftertaste. Its aqueous solubility is

adequate for formulation purposes. It is stable in the solid form, but its stability in solution depends on temperature and pH. It hydrolyzes to aspartylphenylalanine and diketopiperazine, with a loss in sweetness by aspartame synergistic with saccharin, sucrose, glucose, and cyclamate. In addition, its taste can be improved by adding sodium bicarbonate, gluconate salts, and lactose (30).

Flavoring Agents

The flavoring of pharmaceuticals is of great importance to liquid dosage forms intended for oral use in that it can mask the disagreeable taste of drugs (31).

Coloring Agents

Although the use of colorants in medicinal products affords no direct therapeutic benefit, the psychological effects have long been recognized. The appearance of clear liquid products depends primarily on the color and clarity of the solution. Many patients rely on color to recognize the prescribed drug and proper dosage. Unattractive medication can be made acceptable to the patient by careful selection of color. Color is usually

chosen according to the flavor of the product (for example, yellow for lemon or red for cherry).

The current list of Food, Drug, and Cosmetics (FD&C)-certified colorants contains both dyes and lakes. The latter are pigments that are insoluble in water and that impart color by dispersing and reflecting light; they are not used for aqueous solutions. In contrast, FD&C dyes are water-soluble and exhibit color by transmitting light. Dyes should be used at the lowest possible concentration required to produce the desired color; higher concentrations can result in a dull color. Most liquid drug products have dye concentrations of less than 0.001%. Because dyes are usually present in trace amounts, they should be dissolved before mixing with the bulk of the formulation. This ensures complete dissolution before further processing. If dye is added directly to the bulk mixing tank, the presence of small amounts of undissolved materials is difficult to determine and can cause problems later during the compounding. Factors influencing the shade and stability of dyes in liquid systems must be carefully considered. Among these are pH level, microbiological activity, exposure to light in the final package, and compatibility of the dye with other ingredients. Because color shades vary greatly at different pH levels, pH control is extremely important. All soluble dyes contain reactive sites, and some dyes may be incompatible with compounds containing polyvalent cations (such as

calcium, magnesium, or aluminum) and precipitate. Certain dyes, such as FD&C Blue No. 2 and FD&C Red No. 3, exhibit poor stability in aqueous solutions and should never be used for coloring aqueous liquid pharmaceutical products (32).

Preservatives

Liquid oral preparations are the most likely of all nonsterile pharmaceutical products to be contaminated by micro-organisms. Most of these preparations are marketed in a multidose form, enhancing the risk of exposure to microbes. The inclusion of sugars and other excipients enriches the preparation with growth-supporting substrates. The manufacturing process also contributes to possible microbiological contamination. In addition to the risks associated with even purified (USP) water, many raw materials of natural origin are used that may contain a large number of viable spores. Many over-the-counter pharmaceutical products have been prepared traditionally at low costs without sufficient care to prevent microbiological contamination. Therefore, it is essential that these preparations are protected against microbiological deterioration by adequate preservation.

Preservatives must fulfill certain criteria for acceptability. The major factors are those of safety and lack of toxicity after oral intake, particularly because liquid

Table 6 Preservatives used in pharmaceutical systems

Preservative	Usual concentration (%)
Acidic	
Phenol	0.2–0.5
Chlorocresol	0.05–0.1
α -Phenylphenol	0.005–0.01
Alkyl esters of <i>p</i> -Hydroxybenzoic acid	0.001–0.2
Benzoic acid and its salt	0.1–0.3
Boric acid and its salts	0.5–1.0
Sorbic acid and its salts	0.05–0.2
Neutral	
Chlorobutanol	0.5
Benzyl alcohol	1.0
β -Phenylethyl alcohol	0.2–1.0
Mercurial	
Thiomersal	0.001–0.1
Phenylmercuric acetate and nitrate	0.002–0.005
Nitromersol	0.001–0.1
Quaternary ammonium compounds	
Benzalkonium chloride	0.004–0.02
Cetylpyridinium chloride	0.01–0.02

(From Ref. 5.)

Table 7 Buffers commonly used in liquid pharmaceutical products

Buffer	pH	Usual concentration (%)
Acetic acid and a salt	3.5–5.7	1–2
Citric acid and a salt	2.5–6	1–3
Glutamic acid	8.2–10.2	1–2
Phosphoric acid salts	6–8.2	0.8–2

(From Ref. 5.)

medications are often administered to children and the elderly. Preservatives must be soluble, stable, microbiologically active, and compatible with the active ingredient as well as with other components of the formulation.

An ideal preservative that meets all the requirements does not exist. The choice must be made on an individual basis, balancing antimicrobial efficacy against safety. Frequently, a combination of two or more preservatives is needed to achieve the desired efficacy. The antimicrobial preservatives are classified into four major types: acidic, neutral, mercurial, and quaternary ammonium compounds (Table 6) (5).

Acidic preservatives are the most widely used for oral preparations, such as the *p*-Hydroxybenzoic acid esters and the salts of benzoic acid. These are adequately soluble in aqueous systems and possess both antifungal and antibacterial properties. Methyl and propyl *p*-hydroxybenzoic acid are often used together in a ratio of 10:1. The use of more than one ester makes possible a higher total preservative concentration owing to the independent solubilities of each and, according to some researchers, maximizes the antimicrobial effect.

The other three classes of preservatives have been widely used in ophthalmic, nasal, and parenteral products, but not frequently in oral liquid preparations. The neutral preservatives are volatile alcohols; their volatility introduces problems of odor and loss of preservative on aging in multidose preparations. The mercurials and quaternary ammonium compounds are excellent preservatives but are subject to incompatibilities (33). Mercurials are readily reduced to free mercury, and the quaternary compounds are inactivated by anionic substances.

Buffers

Changes in the pH level of a preparation may occur during storage because of degradation reactions within the product, interactions with container components, or dissolution of gases and vapors. To avoid these problems,

buffers are added to stabilize pH levels. A suitable buffer system should have adequate capacity to maintain the pH level of the product during storage. It can be based on the pH profile of the drug in solution. Commonly used buffer systems are acetates, citrates, phosphates, and glutamates (Table 7). Although buffers ensure pH stability, the buffer system can affect other properties such as solubility and kinetics. Buffers can act as general-acid or general-base catalysts and cause degradation of the drug substance. The ionic-strength contributions of the buffer systems can also affect stability. Therefore, the effect of buffer species should be studied before selecting any buffer system.

Antioxidants

Many drugs in solution are subject to oxidative degradation. Such reactions are mediated by free radicals or molecular oxygen and often involve the addition of oxygen or the removal of hydrogen. Drugs possessing favorable oxidation potential are especially vulnerable to degradation. Agents with an oxidation potential lower than that of the drug in question is called antioxidants. They are added to solutions alone or in combination with a chelating agent or other antioxidants and function by being preferentially oxidized and gradually consumed or by blocking an oxidative chain reaction where they are not consumed. Sulfites are the most common antioxidants in aqueous solutions. Irrespective of which sulfite salt is added, the antioxidant moiety depends on its final concentration and the final pH level of the formulation; metabisulfite is used at low pH. A single antioxidant may not provide complete protection. Certain compounds (e.g., ascorbic and citric acids) have been found to act as synergists, increasing the effectiveness of antioxidants, particularly those that block oxidative reactions. Frequently, chelating agents such as ethylenediaminetetraacetic acid derivatives (EDTA) are used in formulations containing trace amounts of heavy metals that would otherwise catalyze oxidative reactions.

Viscosity-Controlling Agents

It is sometimes desirable to increase the viscosity of a liquid to provide or to improve palatability or pourability. This can be achieved by viscosity-controlling agents such as polyvinylpyrrolidone or carboxymethylcelluloses. These compounds give aqueous solutions that are stable over a wide pH range. Methylcellulose and carboxymethylcellulose are available in a number of different

viscosity grades. The latter may be used in solutions containing up to 50% alcohol without precipitating. However, care should be taken to avoid precipitation, which occurs with the insoluble salts to a number of multivalent metal ions such as Al^{3+} , Fe^{3+} , and Ca^{2+} . Methylcellulose polymers do not form insoluble salts with metal ions but can be salted out when the concentration of electrolytes or other dissolved materials exceeds certain limits. These limits may vary from 2 to 40%, depending on the electrolyte and the type of methylcellulose involved. Viscosity-inducing polymers should be used with caution. They are known to form molecular complexes with a variety of organic and inorganic compounds. It is conceivable that highly viscid systems that resist dilution by gastrointestinal fluid may impede drug release and absorption.

MANUFACTURE

The preparation of liquid drug preparations involves choosing the ingredients (using principles already addressed) and the manufacturing equipment. The basic principles involved are the same, regardless of the materials and the quantities involved. Carstensen and Mehta report the scaling-up of solution dosage forms (34), including heating, agitation, and clarification along with basic equations and calculations.

Liquid processing lends itself to computer-controlled automation. A few pharmaceutical firms have already instituted automated or semiautomated processes for several large-selling liquid products (35).

Raw Materials

Although purified water (USP) is required in all operations, it is particularly important in liquid manufacturing. If de-ionized and other water-treatment equipment is used, special attention must be given to routine microbiological and chemical testing. Storage tanks for glycerin and propylene glycol should be constructed to facilitate examination as well as cleaning.

Equipment

Simple solutions are most straightforward to scaleup but require tanks of adequate size and suitable mixing capacity (35). Most equipment should have heating and cooling capabilities for rapid dissolution of formulation components. Adequate transfer systems and filtration equipment are required, but they must be monitored to

ensure that they can clarify the product without removing active or adjuvant ingredients. All equipment must be made of suitable, nonreactive sanitary materials and be designed and constructed to facilitate easy cleaning. Liquid pharmaceutical processing tanks, kettles, pipes, mills, filter housings, and so forth are most frequently fabricated from stainless steel. Of the three types commonly used in the industry (304, 308, and 316), type 316 is most often used because it is the least reactive. Stainless steel is virtually nonreactive but may react with some acidic pharmaceutical liquids (36). This problem can be minimized by treating the stainless steel with acetic acid or nitric acid solution to remove surface alkalinity. This process, known as passivation, may be needed periodically. For example, if an alkaline cleaning agent is used between batches of a reactive product, passivation may be required before the subsequent batch can be prepared.

Interaction with metallic surfaces can be minimized by using polytetrafluoroethylene (Teflon) liners. Although Teflon is inert, these liners have the potential disadvantages of cracking, breaking, flaking, and peeling, with resulting product contamination.

A valuable and practical discussion on the design of piping, valves, mixers, pumps, and controls to produce high-quality liquid products is given by FitzSimon (37).

Methods of Preparation

Dilute solutions of rapidly dissolving materials are prepared by adding the solute to the solvent and agitating until the solution is homogeneous. Heat may be required for more concentrated solutions or when the solute is slow to dissolve. Excipients are usually added in a specified order to increase the rate of dissolution and to facilitate a rapid approach to equilibrium. For this reason, menthol and flavors are charged as alcoholic solutions to the batch. Solutes present in small concentrations, particularly dyes and other intensely colored materials, should be dissolved before mixing with the main portion of the batch to ensure complete dissolution. If the solutes were charged directly to the bulk mixing tank, it would be difficult to detect small amounts of undissolved material at the bottom of the tank. As a rule, complete solution should be confirmed at every stage in the manufacture of a homogeneous liquid. In the laboratory, liquids are usually measured by volume. However, in large-scale production, gravimetric means of measurement are used. For this reason, all liquids components of the formulation are expressed in units of both volume and weight.

Solutions must be filtered and clarified; this stage of the process is called "polishing." A highly polished solution requires the removal of particulate matter down to at least 3 μm . Filters used in the manufacturing, processing, or packing of liquid drug products intended for human use should not release fibers. If a fiber-releasing filter needs to be used, it must be followed by a nonfiber-releasing filter of optimum porosity. Filter aids are commonly used to improve clarity and increase the flow rate, thus decreasing filtration time. The amount and type of filter aid must be determined during the development of the product; the amount usually does not exceed 0.5 g/L. Examples of filter aids are diatomaceous earth, carbon, expanded perlite, and cellulose.

Filling and Sealing

A liquid may be removed from a bulk container in portions to individual-dose containers more easily and uniformly than a solid. Certain fundamental features are found on all machines used for filling containers with liquid. A means is used for repeatedly forcing a measured volume of the liquid through the orifice of a delivery tube designed to enter the constricted opening of a container. The size of the delivery tube is governed by the opening in the container, the viscosity and density of the liquid, and the desired speed of delivery. The tube must freely enter the neck of the container and deliver the liquid deep enough to permit air to escape without sweeping the entering liquid onto the neck or out of the container; the tube should have the maximum possible diameter. Excessive delivery force causes splashing and troublesome foaming if the liquid has a low surface tension.

Small volumes of liquids (usually for pediatric use) are delivered by the stroke of the plunger of a syringe, which forces the liquid through a two-way valve that provides for an alternative filling of the syringe from a reservoir and delivery to a container. For heavy, viscous liquids, a sliding piston valve provides more positive action. A drop of liquid normally hangs at the tip of the tube after a delivery, which is removed by a retraction device. Filling machines should be designed so that the parts through which the liquid flows can be easily dismantled for cleaning. These parts should be constructed of nonreactive materials such as stainless steel. Small-volume filling machines are designed to deliver volume precisely. Syringes are typically also made of stainless steel. The stroke of the syringe can be repeated precisely; therefore, once a particular setting has been calibrated for a delivery, high precision is possible. The precision can be affected by certain operating factors such as the speed of delivery, the

uniformity of speed, the expansion of rubber tubing connecting the valve to the delivery tube, and the rapidity of the action of the valves.

Large-volume filling does not normally require the precision required for small volumes. Therefore, bottles of solution are usually filled by gravity, pressure, or vacuum devices. Gravity filling is relatively slow but simple. The liquid reservoir to a shut-off device at the filling line, which is usually hand-operated; the bottles are filled to a graduation mark. The pressure-pump filler is often operated semiautomatically and differs from the gravity filler principally in that the liquid is under pressure. It is usually equipped with an overflow tube connected to a receiver to prevent excess filling.

Vacuum filling is commonly used for large liquid volumes because it is easily adapted to automation. A vacuum is produced in a bottle when the nozzle gasket makes a seal against the lip of the bottle to be filled. The vacuum draws the liquid from a reservoir through the delivery tube into the bottle. When the liquid level reaches the level of an adjustable overflow tube, the seal is mechanically loosened, and the vacuum is released. Any liquid that has been drawn into the vacuum line is collected in a receiver and returned to the reservoir.

Accuracy and precision of filling with liquids vary with the method. Therefore, a method is selected to provide the degree of accuracy and precision required. A slight excess is required in each container to provide for the loss that occurs at the time of administration resulting from adherence to the wall of the container. The danger of overdose as well as economic factors limits the amount of excess desirable in a given container.

Highly viscous solutions require specially designed equipment. To obtain a reasonable flow rate, high pressure must be applied, or containers with large openings must be used to permit the entry of large delivery tubes. Sometimes jacketed reservoir tanks can be used to raise the temperature of the product and thereby lower its viscosity.

A problem common to all types of machines that fill containers with liquid but that is particularly bothersome in high-speed automatic equipment is excessive foaming. Foaming during the filling operation can be reduced by using filling equipment that minimizes product turbulence, closed-system filling to limit the introduction of air or other gases that cause foaming, mechanical defoaming devices, or reduction in the speed of the filling line. All these methods introduce considerable engineering and production difficulties. It would be preferable to formulate the product with careful consideration of the problems that might eventually be encountered in large-scale production and high-speed filling operations.

A microbial survey should be performed on all packaging materials that come in contact with the product to ensure the absence of microbial contamination. Attention must also be given to details during packaging operations. For example, on small-volume orders, bottle closures or tips for plastic squeeze-spray containers are often placed on the product by hand. This procedure can be a source of microbial contamination unless operators use gloves that are sterilized and disinfected periodically during use.

The University of North Carolina, Chapel Hill, North Carolina, U.S.A.

INTRODUCTION

The range of techniques for the preparation of microspheres offers a variety of opportunities to control aspects of drug administration. The term “control” includes phenomena such as protection and masking, reduced dissolution rate, facilitation of handling, and spatial targeting of the active ingredient. This approach facilitates accurate delivery of small quantities of potent drugs; reduced drug concentrations at sites other than the target organ or tissue; and protection of labile compounds before and after administration and prior to appearance at the site of action.

The characteristics of microspheres containing drug should be correlated with the required therapeutic action and are dictated by the materials and methods employed in the manufacture of the delivery systems.

The behavior of drugs *in vivo* can be manipulated by coupling the drug to a carrier particle. The clearance kinetics, tissue distribution, metabolism, and cellular interactions of the drug are strongly influenced by the behavior of the carrier. Exploitation of these changes in pharmacodynamic behavior may lead to enhanced therapeutic effect. However, an intelligent approach to therapeutics employing drug-carrier technology requires a detailed understanding of the carrier interaction with critical cellular and organ systems and of the limitations of the system with respect to formulation procedures and stability. A variety of agents have been used as drug carriers, including immunoglobulins, serum proteins, liposomes, microspheres, nanoparticles, microcapsules, and even cells such as erythrocytes.

Antineoplastic drugs (1–5), narcotic antagonists (6), steroid hormones (7, 8), luteinizing hormone releasing hormone analogs (9, 10), elastase (11), and other macromolecules (12) have been incorporated into microspheres. In addition, vaccines, living cells, and tissues have been encapsulated.

DEFINITION AND GENERAL DESCRIPTION

Microspheres can be defined as solid, approximately spherical particles ranging in size from 1 to 1000 μm . They are made of polymeric, waxy, or other protective materials, that is, biodegradable synthetic polymers and modified natural products such as starches, gums, proteins, fats, and waxes. The natural polymers include albumin and gelatin (13, 14); the synthetic polymers include polylactic acid and polyglycolic acid (15, 16).

The solvents used to dissolve the polymeric materials are chosen according to the polymer and drug solubilities and stabilities, process safety, and economic considerations. Substances can be incorporated within microspheres in the liquid or solid state during manufacture or subsequently by absorption. Fig. 1 shows two types of microspheres: Microcapsules, where the entrapped substance is completely surrounded by a distinct capsule wall, and micromatrices, where the entrapped substance is dispersed throughout the microsphere matrix.

Microspheres are small and have large surface-to-volume ratios. At the lower end of their size range they have colloidal properties (17). The interfacial properties of microspheres are extremely important, often dictating their activity. In fact, the principle of microsphere manufacture depends on the creation of an interfacial area, involving a polymeric material that will form an interfacial boundary and a method of cross-linking to impart permanency. The methods of manufacturing described later are by no means comprehensive and the reader should bear in mind that if the aforementioned criteria are adhered to, the only limitation to the manufacture of microspheres is the researcher's imagination.

HISTORICAL AND CONTEXTUAL PERSPECTIVE

The concept of packaging microscopic quantities of materials within microspheres dates back to the 1930s and

Fig. 1 Schematic diagram illustrating microspheres. (a) Microcapsule consisting of an encapsulated core particle, and (b) Micromatrix consisting of homogeneous dispersion of active ingredient in particle.

the work of Bungenberg de Jong and coworkers (18) on the entrapment of substances within coacervates. The first commercial application of encapsulation was by the National Cash Register Company for the manufacture of carbonless copying paper (19). The technology and applications have advanced over the last several decades. This technology is used by the agricultural, food, household products, medical, graphics, and cosmetics industries.

The potential use of microspheres in the pharmaceutical industry has been considered since the 1960s (20–22) for the following applications:

- Taste and odor masking
- Conversion of oils and other liquids to solids for ease of handling
- Protection of drugs against the environment (moisture, light, heat, and/or oxidation) and vice versa (prevention of pain on injection) (23)
- Delay of volatilization
- Separation of incompatible materials (other drugs or excipients such as buffers)
- Improvement of flow of powders
- Safe handling of toxic substances
- Aid in dispersion of water-insoluble substances in aqueous media, and
- Production of sustained-release, controlled-release, and targeted medications (24–27)
- Reduced dose dumping potential compared to large implantable devices

Microencapsulation has also been used medically for the encapsulation of live cells and vaccines. Biocompatibility can be improved by the encapsulation of artificial cells and biomolecules such as peptides, proteins, and

hormones (28, 29), which can prevent unwanted immunological reactions that would lead to inactivation or rejection. Microspheres are used for isolating materials until their activity is needed. The biotechnology industry employs microspheres to contain organisms and their recombinant products to aid in the isolation of these products (30).

PHARMACEUTICAL APPLICATIONS

A number of pharmaceutical microencapsulated products are currently on the market, such as aspirin, theophylline and its derivatives, vitamins, pancrelipase, antihypertensives, potassium chloride, progesterone, and contraceptive hormone combinations (31).

Microencapsulated KCl (Micro-K, R.H. Robins, Richmond, VA) is used to prevent gastrointestinal complications associated with potassium chloride. The dispersibility of the microcapsules and the controlled release of the ions minimize the possibility of local high salt concentrations, which could result in ulceration, hemorrhage, or perforation. Microspheres have also found potential applications as injection (32, 33) or inhalation (34–37) products. The number of commercially available products does not reflect the amount of research that has been carried out in this area, nor the benefits that can be achieved using this technology. Economic considerations have been a key factor in determining the number of pharmaceutical microencapsulated products. Most encapsulation processes are expensive and require significant capital investment for equipment. An exception is pan or spray coating and spray drying, since the necessary equipment may already be available within the company. An additional expense is due to the fact that most microencapsulation processes are patent protected.

OTHER APPLICATIONS

Applications of microencapsulation in other industries are numerous. The best known microencapsulated products are carbonless copying paper, photosensitive paper, microencapsulated fragrances, such as “scent-strips” (also known as “snap-n-burst”), and microencapsulated aromas (“scratch-n-sniff”). All of these products are usually prepared by gelatin–acacia complex coacervation. Scratch-n-sniff has been used in children’s books and food and cosmetic aroma advertising (38). Microcapsules are also extensively used as diagnostics, for example,

temperature-sensitive microcapsules for thermographic detection of tumors (39).

In the biotechnology industry microencapsulated microbial cells are being used for the production of recombinant proteins and peptides (30). The retention of the product within the microcapsule can be beneficial in the collection and isolation of the product. Encapsulation of microbial cells can also increase the cell-loading capacity and the rate of production in bioreactors. Smaller microcapsules are better for these purposes; they have a larger surface area that is important for the exchange of gases across the microcapsule membrane. Microcapsules with semipermeable membranes are being used in cell culture (40). A feline breast tumor line, which was difficult to grow in conventional culture, has been successfully grown in microcapsules (41). Microencapsulated activated charcoal has been used for hemoperfusion (29). Paramedical uses of microcapsules include bandages with microencapsulated anti-infective substances (25). A unique application of microencapsulation technology is for feeding organisms. Sea bass larvae have been fed with all-protein microcapsules or with microcapsules containing lipids to supplement their diet (42).

MICROSPHERE MANUFACTURE

The most important physicochemical characteristics that may be controlled in microsphere manufacture are:

- Particle size and distribution
- Polymer molecular weight
- Ratio of drug to polymer
- Total mass of drug and polymer

Each of these can be related to the manufacture and rate of drug release from the systems. The following discussion presents methods of manufacture of coated or encapsulated systems, referred to as microcapsules, and matrix systems containing homogeneously distributed drug, referred to as micromatrices.

Wax Coating and Hot Melt

Wax may be used to coat the core particles, encapsulating drug by dissolution or dispersion in the molten wax. The waxy solution or suspension is dispersed by high speed mixing into a cold solution, such as cold liquid paraffin. The mixture is agitated for at least one hour. The external phase (liquid paraffin) is then decanted and the microcapsules are suspended in a nonmiscible solvent, and allowed to air dry. Multiple emulsions may also be formed (43). For example,

a heated aqueous drug solution can be dispersed in molten wax to form a water-in-oil emulsion, which is emulsified in a heated external aqueous phase to form a water-in-oil-in-water emulsion. The system is cooled and the microcapsules collected. For highly aqueous soluble drugs, a nonaqueous phase can be used to prevent loss of drug to the external phase (44). Another alternative is to rapidly reduce the temperature when the primary emulsion is placed in the external aqueous phase.

Wax coated microcapsules, while inexpensive and often used, release drug more rapidly than polymeric microcapsules. Carnauba wax and beeswax can be used as the coating materials and these can be mixed in order to achieve desired characteristics (45). Wax-coated microcapsules have been successfully tableted. Small aerosol particles, 1–5 μm in diameter, have been condensation coated from a vapor of a fatty acid or paraffin wax (46, 47). These particles have been shown to exhibit reduced dissolution rates in vitro, corresponding to reduced absorption rates following deposition in the lungs of Beagle dogs.

Polyanhydrides (48) have been chosen for the preparation of microspheres because of their degradation by surface erosion into apparently nontoxic small molecules (49, 50). The mixture of polymer and active ingredient is suspended in a miscible solvent, heated 5°C above the melting point of the polymer and stirred continuously. The emulsion is stabilized by cooling below the melting point until the droplets solidify.

Spray Coating and Pan Coating

Spray coating and pan coating employ heat-jacketed coating pans in which the solid drug core particles are rotated and into which the coating material is sprayed. The core particles are in the size range of micrometers up to a few millimeters. The coating material is usually sprayed at an angle from the side into the pan. The process is continued until an even coating is completed. This is the process typically used to coat tablets and capsules.

Coating a large number of small particles may provide a safer and more consistent release pattern than coated tablets. In addition, several batches of microspheres can be prepared with different coating thicknesses and mixed to achieve specific controlled release patterns.

The Wurster process, a variation of the basic pan coating method, is an adaptation of the fluid-bed granulator (51, 52). The solid core particles are fluidized by air pressure and a spray of dissolved wall material is applied from the perforated bottom of the fluidization chamber parallel to the air stream and onto the solid core particles. Alternatively, the coating solution can be

sprayed from the top or the sides into an upstream of fluidized particles. This adaptation allows the coating of small particles (53). The fluidized-bed technique produces a more uniform coating thickness than the pan-coating methodology. Problems can arise with inflammable organic solvents because of the high risk of explosion in the enclosed fluidizer chamber. Explosion proof units have been designed; however, over the past two decades aqueous coating solutions are being used more and more.

Examples of aqueous coating solutions include water-soluble low molecular weight cellulose ethers (54, 55), emulsion polymerization latexes of polymethacrylates (56), and dispersions of water-insoluble polymers such as ethylcellulose in the form of pseudolatex (57). These solvent-free coating solutions provide a range of different coatings from fast disintegrating isolating layers to enteric and sustained-release coatings. Lehmann has reviewed different commercial methods, the conditions required for coating, and various coating formulas including illustrations of the types of equipment used (58).

Coacervation

Coacervation is the simple separation of a macromolecular solution into two immiscible liquid phases, a dense coacervate phase, which is relatively concentrated in macromolecules, and a dilute equilibrium phase (18). Coacervates may be described as liquid crystals and mesophases. In the presence of only one macromolecule, this process is referred to as simple coacervation. When two or more macromolecules of opposite charge are present, it is referred to as complex coacervation (18). Simple coacervation is induced by a change in conditions, which results in dehydration of the macromolecules. This may be achieved by the addition of a nonsolvent, the addition of microions, or a temperature change, all of which promote polymer-polymer interactions over polymer-solvent interactions. Complex coacervation is driven by electrostatic interactive forces between two or more macromolecules (59).

Bungenberg de Jong et al. (60) first showed that solid particles could also be entrapped in coacervate systems. On phase separation by simple or complex methods tiny coacervate droplets are formed, which sediment or coalesce to form a separate coacervate phase. The coacervate forms around any core material that may be present, such as drug particles (Fig. 2). Agitation of the coacervate system can prevent coalescence and sedimentation of the droplets, which can be cross-linked to form stable microcapsules by addition of an agent, such as

Fig. 2 Schematic diagram of the formation of a coacervate around a core material.

glutaraldehyde, or the application of heat (14, 24, 61, 62). Drug microencapsulation by coacervation has been reviewed by Madan (62) and by Nixon (24).

The large number of variables involved in complex coacervation (pH, ionic strength, macromolecule concentration, macromolecule ratio, and macromolecular weight) (18, 63) affect microcapsule production, resulting in a large number of controllable parameters. These can be manipulated to produce microcapsules with specific properties. Complex coacervate microcapsules have been formulated as suspensions or gels (64), and have been compounded within suppositories (65, 66) and tablets (66, 67).

Although many successful coacervate microencapsulation systems have been prepared, coacervate microcapsules have a number of limitations. They can be produced only at specific pH values, they require stabilization by cross-linking agents or heat, and the retention of the encapsulant depends on the extent of cross-linking. The pH limitation can be overcome to some extent by the addition of water-soluble nonionic polymers, such as polyethylene oxide or polyethylene glycol (68, 69). The presence of a small amount of these polymers allows microencapsulation to occur over an expanded pH range. For example, the pH range for coacervation of gelatin and acacia can be extended from pH 2.6–5.5 (63) to pH 2–9 (68). In addition, these polymers induce simple coacervation (68), as has been shown for macromolecules such as gelatin, carboxymethylcellulose, and ethylene-maleic anhydride copolymer. The pH range for simple coacervation is also expanded in the presence of these water-soluble nonionic polymers. For example, the pH range for simple coacervation of gelatin can be increased from only pH values close to the isoelectric point to the pH range of 5.5–9.5 (68).

Cross-linking of coacervates is necessary to stabilize coacervate emulsion droplets and hence form microcapsules. Both chemical cross-linking agents and the application of heat may be harmful to the encapsulant materials, such as thermolabile and chemically labile drugs and live cells. A stable coacervate system, formed without the use of chemical cross-linking agents or the application of heat, has been developed by Burgess and Singh (70, 71). This system is potentially useful for the delivery of protein and polypeptide drugs and other materials unable to withstand cross-linking procedures.

Calcium Alginate Microcapsules

Dropping or spraying a sodium alginate solution into a calcium chloride solution produces microcapsules. The divalent calcium ions cross-link the alginate, forming gelled droplets. These gel droplets can be permanently cross-linked by addition to a polylysine solution. Lim and Sun (72) developed this method for the encapsulation of live cells. Variations on this method with different polymers have been developed. Chitosan is a preferred polymer, because it has a better biocompatibility than alginate (73). Traditionally alginate beads were formed by dropping the alginate solution into the calcium chloride with a fine-bore pipette. However, the droplets were relatively large, because the drops do not fall until they reach a critical mass. Smaller droplets can be formed by using a pump to force the alginate through the pipette (72), a vibration system to help remove the drops from the end of the pipette (72), and an air atomization method (74).

Spray Drying

Spray drying is a single-step, closed-system process applicable to a wide variety of materials, including heat-sensitive materials. This process is often used commercially since the necessary equipment is frequently available at the manufacturing site. As a closed system, it is ideal for good manufacturing practice and the production of sterile materials. The drug and the polymer coating materials are dissolved in a suitable solvent (aqueous or nonaqueous) or the drug may be present as a suspension in the polymer solution. Alternatively, it may be dissolved or suspended within an emulsion or coacervate system. For example, biodegradable polylactide microcapsules can be prepared by dissolving the drug and polymer in methylene chloride (75). Methylcellulose and sodium carboxymethylcellulose spray-dried microspheres are prepared

Fig. 3 Scanning electron micrograph of poly(lactic acid) microspheres containing phenolphthalein prepared by the solvent evaporation method (77). Magnification $\times 4000$.

by dissolving the polymers in aqueous systems. The microsphere size is controlled by the rate of spraying, the feed rate of the polymer drug solution, the nozzle size, the temperature in the drying and collecting chambers, and the size of these two chambers. The quality of spray-dried products is improved by the addition of plasticizers (76) that promote polymer coalescence and film formation and enhance the formation of spherical and smooth-surfaced microcapsules.

Solvent evaporation

This is one of the earliest methods of microsphere manufacture. The polymer and drug must be soluble in an organic solvent, frequently methylene chloride. The solution containing the polymer and the drug may be dispersed in an aqueous phase to form droplets. Continuous mixing and elevated temperatures may be employed to evaporate the more volatile organic solvent and leave the solid polymer–drug particles suspended in an aqueous medium. The particles are finally filtered from the suspension. Fig. 3 shows poly(lactic acid) particles prepared in this manner (77).

Precipitation

Precipitation is a variation on the evaporation method. The emulsion consists of polar droplets dispersed in a nonpolar medium (78). Solvent may be removed from the droplets by the use of a cosolvent. The resulting increase in the polymer drug concentration causes precipitation forming a suspension of microspheres.

Freeze Drying

This technique involves the freezing of the emulsion (78); the relative freezing points of the continuous and dispersed phases are important. The continuous-phase solvent is usually organic and is removed by sublimation at low temperature and pressure. Finally, the dispersed phase solvent of the droplets is removed by sublimation, leaving polymer-drug particles.

Chemical and Thermal Cross-Linking

Microspheres made from natural polymers are prepared by a cross-linking process; polymers include gelatin, albumin, starch, and dextran. A water–oil emulsion is prepared, where the water phase is a solution of the polymer that contains the drug to be incorporated. The oil phase is a suitable vegetable oil or oil-organic solvent mixture containing an oil-soluble emulsifier. Once the desired water–oil emulsion is formed, the water soluble polymer is solidified by some kind of cross-linking process. This may involve thermal treatment (79) or the addition of a chemical cross-linking agent such as glutaraldehyde to form a stable chemical cross-link as in albumin (80). If chemical or heat cross-linking is used, the amount of chemical and the period and intensity of heating are critical in determining the release rates and swelling properties of the microspheres (79). If glutaraldehyde is the cross-linking agent, residual amounts can have toxic effects.

NANOPARTICLES

Nanoparticles, 10–1000 nm polymeric particles, are prepared from the same natural and synthetic biodegradable polymers as microspheres (81–83). Albumin nanoparticles are prepared by the cross-linking processes mentioned previously. For the preparation of particles from synthetic polymers, heterogeneous bulk polymerization techniques of suspension, emulsion, and micelle polymerization are often used.

Suspension polymerization of water-insoluble liquid monomer and drug may be achieved by agitating a dispersion of droplets, 10–1000 nm in diameter, in a continuous aqueous phase (84). The temperature must be carefully controlled. An initiator is frequently employed to increase the reaction rate in the droplets, and the aqueous phase may contain stabilizers to prevent coalescence and thickening agents to increase the viscosity. The polymer is formed by reaction of the functional groups of the monomer. This process has the advantage that the

continuous phase absorbs the heat of the polymerization reaction and minimizes the temperature change within the droplets. However, aggregation of the particles may arise as the polymer molecules in suspended particles coalesce. Unfortunately, it is difficult to eliminate stabilizers and additives, used to prevent coalescence, from the final product.

Emulsion polymerization involves the dispersion of the monomer liquid in an aqueous phase to form droplets, 0.05–5 μm in diameter (85–88). An initiator and a surfactant, in a concentration higher than its critical micelle concentration, are present in the aqueous phase. Excess surfactant molecules form micelles whose hydrophobic interiors take up part of the available monomer, causing them to swell. Initiator radicals diffuse into these swollen micelles and begin the polymerization process. As the monomer is consumed, it is replaced by progressive diffusion of the remaining monomer from its location in the emulsified droplets to the interior of the micelles. The micelles continue to swell in size as polymerization proceeds. The enlarging surfaces compete for available surfactant, thus influencing the number of available micelles that can participate in the polymer formation. This method yields particles of very small size and predictable number at low temperatures. However, the particles usually have a high concentration of associated monomer, which may be toxic.

Micelle polymerization differs from emulsion polymerization in that all of the monomer and the drug is contained within micelles composed of surfactant. Diffusion of the monomer from the micelles is prevented by the nonsolvent properties of the outer phase. Therefore, the increase in particle size is negligible as the polymerization proceeds.

CHARACTERIZATION

Materials

The polymer employed to prepare microspheres must be characterized in terms of molecular weight and purity (89, 89–91), however this topic is beyond the scope of this article. Characterization of the materials may have implications for the formation of the microspheres. The viscosity and film-forming properties of the polymers used should be known. Viscosity can affect the tendency to form microspheres, their size, and even their shape. Burgess and coworkers (70, 92) have shown that albumin–acacia coacervates do not form microcapsules under certain conditions of pH and ionic strength, if the viscosity

of the coacervate phase is too high. Burgess and Carless (63) developed a method to predict the optimum conditions for complex coacervation based on the charge carried by the two polymers involved.

Microspheres

Size characterization may be conducted by various methods including light microscopy, resistance blockage techniques (Coulter analysis), light blockage techniques, light scattering, laser diffraction analysis, and for particles less than 1 μm , photon correlation spectroscopy. Electron microscopy, scanning electron microscopy, and scanning tunneling microscopy are used for surface characterization of microspheres. Fourier transform Raman spectroscopy or X-ray photoelectron spectroscopy may be used to determine if any of the material which should have been entrapped is present on the surface and if any other contaminants are present (93, 94). Other surface characterization techniques include surface charge analysis using microelectrophoresis. Surface charge can provide information regarding microsphere aggregation (14, 95). Surface charge is an important parameter with respect to the interaction of microspheres within the body (96).

Surface forces are important in the entrapment, wetting, and adhesion of core material by the coating material. The wettability of solids by different liquids is usually assessed by contact-angle measurement (97, 98). When wetting of the core material is poor, it is difficult or impossible to form microcapsules. For example, Eudragit RS dissolved in THF-cyclohexane failed to encapsulate charcoal particles but was successful in encapsulating potassium dichromate (99, 100). The surface hydrophobicity of oil droplets has been shown to affect their uptake into complex coacervate droplets (101). Oil uptake was directly related to the hydrophile-lipophile balance (HLB) value at the droplet interface. Additives, such as surfactants, which alter surface properties were shown to affect the uptake of core materials.

Biological Distribution

The disposition of microspheres upon entry to the body has been studied extensively. They are frequently labeled with a radionuclide to allow study by scintillation counting or scintigraphy (23). This work has largely focused on tissue distribution as a function of particle size, with the conclusion that particles below 7 μm tend to locate predominantly in the reticuloendothelial system of the liver, whereas particles 7–15 μm in size tend to be collected in the capillary system of the lung (77). The

acute toxicity (102), tissue interaction (103–105), cell interaction (106–108), and protein interaction (109) of various microspheres have been investigated. These studies demonstrated that the toxicity of microspheres is related to the number and size administered. Initial inflammatory responses to the administration of microspheres were consistent with observations that phagocytosis by neutrophils and macrophages may occur. The extent and nature of the cell and tissue effects of microspheres may be related to the surface characteristics of the polymer employed and to the particle size. For example, fibrinogen has been shown to associate with poly-DL-lactide microcapsules, affecting the surface-charge characteristics (104). This phenomenon is related to the hydrophobic nature of the surface. Indeed, hydrophilic coatings can reduce the uptake of microspheres by the liver and peritoneal macrophages (110–112).

THERAPEUTIC APPLICATIONS

Targeting

Drugs can be targeted to specific sites in the body using microspheres and other colloidal carrier systems. Targeting by colloid delivery systems is dealt with elsewhere in this encyclopedia (17). Targeting by microspheres may be passive, active, diversional, or physical. In passive targeting the microspheres follow their natural distribution in the body (which depends on particle size, shape, surface characteristics, particle deformation, and route of administration). In active targeting the natural distribution of the microspheres is altered (for example, by attachment of site-specific vectoring agents such as monoclonal antibodies and lectins). Diversional targeting means blocking the natural distribution of the microspheres, for example, partly or completely impairing the cells of the reticuloendothelial system, which would otherwise take up the microspheres. Physical targeting involves an external influence, such as a change in temperature or a magnetic field to direct the microspheres to the desired site.

Degrees of targeting can be achieved by localization of the drug to a specific area in the body, to a particular organ in the body (for example, the lungs), to a particular group of cells within the body (for example, the Kupffer cells), and even to intracellular structures (such as the lysosomes or the cell nucleus). The problems associated with directing microspheres to specific areas in the body following parenteral administration are discussed in the article Colloids and Colloid Drug Delivery in this encyclopedia (17).

Oral targeting can be achieved using microspheres; those less than 10 μm in diameter have been shown to target the Peyer's patch (113). Microspheres less than 5 μm were shown to be transported through the lymphatics within macrophages and those larger than 5 μm remained in the Peyer's patch (113). Toxoid vaccine microcapsules were effectively delivered and released in the gut-associated lymphoid tissue following oral administration (114).

Controlled Release

The rate of drug release from microspheres dictates their therapeutic action. Release is governed by the molecular structure of the drug and polymer, the resistance of the polymer to degradation, and the surface area and porosity of the microspheres (16, 115, 116). Reservoir delivery systems extend the residence time of drug within the systemic circulation and were originally focused on zero-order dissolution kinetics. This mathematical expression describes a linear relationship between rate of appearance in plasma and time. Ideally, the plasma drug concentration is independent of time for most of the dissolution period and is optimally maintained in the therapeutic window.

In nonporous polymeric systems the rate of drug release is dictated by the device surface area which is linked directly to its shape. Drug release from polymeric systems with a variety of geometries has been described (117). Zero-order release kinetics may be more easily achieved with slab or rod geometries than spheres. The rate of release from spheres may result from polymer diffusion or erosion (116, 118, 119). Diffusion-mediated release has been studied extensively and described mathematically (120, 121).

The internal structure of microspheres may vary as a function of the microencapsulation process employed (122). Reservoir microcapsules have a core of drug coated with a polymer. The drug is distributed homogeneously throughout the polymeric matrix in monolithic microspheres.

Controlled drug release from microspheres occurs by diffusion of drug through a polymeric excipient, diffusion of entrapped drug as the polymer erodes, and release of drug through pores in the polymeric microspheres. If the drug is released by diffusion through the polymer without erosion, the release depends on the surface area of the microspheres and the path length of the drug in transit to the surrounding environment. For example, increasing the surface area, by reducing particle size, results in an increased release rate. The path length of motion for the drug in the matrix can be controlled by manipulating the microsphere loading. Microspheres with a high drug

content release the active ingredient more rapidly than those with a low load. Physicochemical properties of the drug and excipient such as permeability of one in the other, identity of the polymer, degree of crystallinity, inclusion of plasticizers and fillers, and thickness of the polymer influence the drug release rate.

Release from reservoir microcapsules

The factors affecting drug release may be elucidated by a study of drug release from the simplest system, a reservoir microcapsule. Diffusion of drug through such a structure may involve transport not only through an isotropic medium, such as the drug in solution, but also through a polymeric membrane. Transport of drug through such a membrane involves dissolution of the drug in the polymer at the high-concentration side of the membrane interface and diffusion across the membrane in the direction of decreasing concentration. In addition, the concentration difference across the membrane, which is taken as the driving force for drug transport, tends to decrease as the solubility of the drug on the upstream side of the membrane decreases. Therefore, the dissolution rate of poorly soluble drugs can be an important factor in limiting drug release.

Consider a spherical reservoir device where the thermodynamic activity of the core material is maintained constant within the device, and the coating is inert, homogeneous, and of uniform thickness. The steady-state release rate derived from Fick's law is

$$\frac{dM}{dt} = 4DKC \frac{r_o, r_i}{r_o - r_i} \quad (1)$$

where r_o and r_i are the outside and inside radii, respectively, D is the diffusion coefficient of the drug molecule, K is the partition coefficient, and C is the concentration difference between either side of the coating. Assuming all parameters on the right side of Eq. 1 remain constant, consistent with no change in activity of the core material, C does not change. Integration of Eq. 1 over a finite period of the steady state would indicate that the drug release was zero-order. This is explained by the pathlength and surface area remaining constant since the membrane the drug has to traverse is of uniform thickness. If, however, the thermodynamic activity of the core material does not remain constant, then release is first-order.

It may be necessary to consider the effect of a boundary layer on the release rate. A boundary layer of appreciable drug concentration on the surface of the device would hinder drug release by diffusion. The effect of the layer is more marked with drugs of low solubility and with microparticles having irregular surfaces. From this simple

example, it can be seen that various factors affect the release rate from reservoir microcapsules.

Release from monolithic micromatrices

In a monolithic microsphere the path length does not remain constant, since the drug in the center has a longer path to travel than the drug near the surface, and therefore the rate of release decreases exponentially with time.

Nevertheless, monolithic microspheres can be made to release drug at an approximately constant rate (117, 123). The core loading of these microspheres may be increased to create structures similar to those of reservoir microcapsules. An optimum combination of particle sizes (a size distribution), may be prepared to achieve a constant rate of drug release. Preparing microspheres with an erodible polymer in such a way that maximum erosion occurs in conjunction with minimum diffusion may establish a constant release rate. Although the principles described here appear simple, they are difficult to utilize because of their dependence on a number of factors, each of which can complicate the process.

Live-Cell Encapsulation

Microcapsules have been investigated as potential artificial cells [first demonstrated by Chang in 1964 (124)] and as a means to immobilize live cells (72). Potential medical applications of artificial cells have been investigated such as artificial liver, artificial kidney, and red blood cell substitutes. The encapsulation of living cells has been investigated as a means to transplant tissues without immune rejection. The capsule membrane must be semipermeable in order to be impermeable to high molecular weight antibodies, which would cause rejection or destruction of the transplanted cells, but be permeable to lower molecular weight species such as oxygen, nutrients, and internally generated therapeutic agents (for example, hormones such as insulin). The encapsulation process must not be harmful to the cells and therefore must not involve harsh conditions, such as those caused by the use of organic solvents and heat during processing. The finished microcapsules must be sterile, stable, and biocompatible. The encapsulation of mammalian cells is more difficult than that of microbial cells since their membranes are more fragile, and these must be preserved during encapsulation. The temperature, pH, ionic strength, and toxicity of solvent and reagent must be carefully controlled. A common method of microencapsulating live cells is to entrap the cells in a protective gel and form a permanent membrane around the gel droplets. A calcium alginate gel method was developed by Lim and Sun (72), has been successfully

applied to mammalian cells. A microencapsulation system combining the easy setting characteristics of alginate and the stability and biocompatibility of hydrogel polymers has been devised (125, 126); it involves an alginate-HEMA graft copolymer.

Immobilized islets of Langerhans are able to respond to external glucose concentrations and release insulin into the systemic circulation (72). A number of animal studies have shown that alginate-polylysine encapsulated pancreatic islets were successful in correcting the diabetic state in rats for periods of two to three weeks (127).

Immobilized cells are also used in biotechnology in the production of protein molecules. For example, entrapped hybridoma cells have been used for the production of monoclonal antibodies (30) which are secreted into the microcapsules. This allows for easier collection of the antibodies compared to growing the hybridoma cells directly in the culture medium. The microcapsules are easily separated from the culture medium and broken to collect the antibodies. Isolation of the antibodies from the culture medium involves numerous purification steps, and product is lost during each of these steps to an extent which depends on the efficiency of the process. Live vaccines have been encapsulated. For example, *Bacillus Calmette Guerin* has been encapsulated in an alginate polylysine-alginate system (74).

STERILIZATION

Microspheres that are administered parenterally must be sterile. Sterilization is usually achieved by aseptic processing. The final product may not be able to undergo terminal sterilization, which may be detrimental to the delivery system, altering the release pattern or destroying the targeting properties. In addition, the entrapped drug or biological substance may not be able to withstand the heat of sterilization. Although the exterior of the microspheres can be investigated for sterility by conventional plating methodology, it is difficult to determine whether the interiors of the microspheres are free from contamination. The microspheres can be broken, although this introduces the possibility of false positive or false negative results. A method has been developed whereby the presence of viable organisms in the interior of microsphere systems can be determined without breaking the microcapsules using a detection method for organism metabolism (128).

Sterilization is one of many aspects that must be addressed when considering microspheres for commercial purposes (129). The development of a product is achieved most effectively by parallel approaches to formulation and

process design. Very little has been published with regard to industrial-scale manufacturing of microspheres for the delivery of pharmaceuticals.

MICROBIOLOGIC MONITORING OF CONTROLLED PROCESSES

Gregory F. Peters

Marghi R. McKeon

Lab Safety Corp., Des Plaines, Illinois, U.S.A.

INTRODUCTION

Microbiologic monitoring of controlled pharmaceutical and medical device manufacturing, and pharmacy compounding processes, is mandated in numerous standards and guidelines (1–3), although procedures, limits, and frequencies are not well defined (4). Because many characteristics of microbiologic sampling limit its value as a monitoring method (5), efforts to detect contamination in controlled environments require carefully developed and executed sampling plans to produce reliable data that confirm the acceptability of operating conditions.

Monitoring of any controlled process is a component of an outcome-producing, closed-loop system for assuring continued operation of critical processes in accordance with validated design conditions. To achieve this goal, a monitoring plan must be developed, conducted, and evaluated within the context of a Validation and Monitoring protocol. All results must be related to the original validated process, either as evidence that it continues to operate within acceptable limits, or as a means of detecting shifts in the process that might impinge on product quality. Ideally, monitoring results will also provide information that will be useful in determining the cause of such shifts.

The objectives of the monitoring plan within the validation and monitoring system for quality management must be clearly defined so that the information collected will be relevant to system goals. The limitations of sampling equipment and methods must be taken into consideration when developing the sampling plan and interpreting results. The underlying causes for shifts in various monitoring results must be understood in order to facilitate development of effective corrective action plans.

VALIDATION AND MONITORING RATIONALE

The regulatory requirements for validation of pharmaceutical aseptic processes are clear (6). Generally accepted

quality assurance principles require initial demonstration of the efficacy of any process (*validation*), followed by regular, periodic observation to demonstrate that the process continues to operate in accordance with validation conditions (*monitoring*).

Validation usually consists of a series of “worst-case” process simulations, wherein a sterile growth medium is substituted for product to demonstrate that processing consistently yields products of acceptable quality (6). During this Process Qualification (PQ) phase, variable conditions that might effect product quality are carefully defined, controlled, monitored, and documented, and the assumption is reasonably made that the process will then yield the same product quality achieved during the PQ, so long as all variable factors are controlled to duplicate validation conditions. This assumption is based upon the results of monitoring data obtained from a variety of sources. The validity of the assumption of acceptable quality is, therefore, dependent upon the reliability of the monitoring data as a measure of control of process variables.

Validation Protocol

The validation protocol should define the manufacturing or compounding process, its purpose in terms of the desired positive impact on product quality, and how that impact will be demonstrated. The protocol should include the following components:

1. A description of the product, and applicable release criteria including AOQL/ROQL;
2. The facility design rationale for maintaining process integrity, including identification and elimination of inaccessible areas that may be difficult to decontaminate, enumeration of the clean-space engineering controls, and how these controls will be applied, tested, and monitored;
3. A schematic description of the aseptic process and the critical work surfaces, work zones, and support areas, including the designation of particulate cleanliness class (7), microbial target values (8, 9) (Table 1), and

Table 1 Process monitoring targets/frequency

- engineering control equipment validation methods^a (10);
4. The selection and justification of gowning and barrier techniques to ensure adequate isolation of personnel, based upon industry standards (3) and process requirements;
 5. A definition of the aseptic techniques and work practices of operative personnel, and a report of findings based upon videotaped observation of the actual work stream during prequalification runs for identification and elimination of personnel-generated contamination sources, identification of susceptible areas including critical sites and steps, and indicator sites;
 6. A description of sanitizing methods and sanitizing compound validation;
 7. A definition of the equipment and methods to be used in assuring reliable test data; and
 8. All test data, including instrument calibrations, testing and certification reports, and statistical justification.

Monitoring Plan

Following evaluation of all environmental monitoring data collected during the PQ, a monitoring plan (11) defining ongoing monitoring procedures, locations, and frequency should be implemented. The PQ data from product testing should be compared to environmental and process monitoring results to determine the monitoring sites and methods that best correlate with shifts in product quality. The plan should

1. Assure specified, periodic monitoring of critical manufacturing or compounding process parameters at critical points during periods of peak activity, and establish the circumstances and frequency with which monitoring is to be carried out to assure a reliable basis for claiming process control.
2. Provide for standardized, quantitative microbiologic sampling of process air, environmental surfaces, and personnel barriers, as well as sampling of other, related parameters.
3. Include sampling location maps, sample sizes, probe heights, methods, equipment, and frequency during

^aValidation testing of HEPA filters requires an exacting aerosol challenge of 100% of the filtration media, frame, and locking device in accordance with Secs. 40 and 50 F.S. 209b (18). Successful testing in this manner establishes control of the "first air" emanating directly from the filter, as it approaches the entrance plane within the unidirectional slipstream, to better-than-Class I conditions. Monitoring of HEPA filters in accordance with F.S. 209e (7) involves an average of DPC readings derived from a number of representative locations to assure Class 10 or 100 conditions at the entrance plane of the unidirectional slipstream (10)

manufacturing operations, and a method for statistical justification of results.

4. Include alert and action limit criteria for acting upon ongoing monitoring information.
5. Include a system for evaluating and modifying the monitoring plan to assure collection of reliable, useful data, and
6. Include a corrective action plan, and methods of verifying the efficacy of any corrective actions taken.

Limitations of Microbiologic Monitoring

The minimum media-fill validation requirement of not more than one sterility failure per thousand units, representing the minimum sterility assurance level of 10^{-3} (>99.9%) is the only microbiologic limit in the validation and monitoring scheme that is based upon demonstrated product quality. Achievement of this sterility assurance level represents the aggregate impact of all process design and control factors, including sampling and attendant laboratory procedures. [This limit, however, probably does not reflect the true integrity of a valid aseptic process (12).] All other limits are indices, which are used indirectly to demonstrate that the process is under control as validated. Because all environmental monitoring is necessarily performed at some point downstream and apart from the product, no absolute evaluation of product quality is obtainable through monitoring procedures, however intensive. In addition, testing and monitoring methods do not always parallel or identify the pathways through which contaminants are introduced into the product.

Difficulty in validating microbiologic monitoring methods results from a lack of comprehensive testing standards, reliable test equipment, and reliable methods for correlating sample data to predictions of product quality. Several characteristics and qualities of both contamination events and sampling methods limit the usefulness of microbiologic monitoring as a method of determining the acceptability of a specific product batch:

1. Microbiologic contamination events in controlled facilities are usually not randomly distributed in time, space, or by type of organism;
2. No single sampling method repeatedly recovers a known and consistent percentage of all types of organisms;
3. For most types of contamination detected, there are usually many possible sources, not the least of which are the sampling personnel, equipment, and lab processing; and
4. An extended interval is required for development of results.

Perspectives

These considerations underscore recent concerns that regulatory groups may require that unreliable environmental monitoring data be used as release criteria (15). Current industry standards and regulatory guidelines do not, and should not be interpreted to condone the rejection of batches on the basis of absolute environmental counts alone. Microbiologic monitoring is employed for practical reasons, not because it is ideal or unique in detecting shifts in process conditions.

Regulatory agencies and auditors understandably seek easy-to-interpret data as a basis for decisions regarding product acceptability, and are becoming increasingly hesitant to accept product release in the absence of demonstrable levels of microbiologic control. Conversely, industry is justifiably reluctant to set microbiologic monitoring limits because regulators may misinterpret their meaning in a quality assurance (QA) context. The failure to meet process control limits is quite different from the failure to meet product specifications. Failure to meet a monitoring limit means only that monitoring data can no longer demonstrate validation conditions, and product quality *may* be adversely affected. Enhanced product testing or other corrective actions may be indicated, but batch rejection should not be extrapolated from QA monitoring results, alone.

Setting Limits

In the QA context, limits are established to trigger specific actions, or outcomes. The alert (warning) limit is the point at which the operator should become alerted to the possibility of a deteriorating trend. When an action limit is exceeded, the operator must take action to identify and correct the condition(s) that are causing a verified trend before a "fail" limit is reached and the data fail to indicate process control and support continued production. In a well-designed and executed process, however, such a fail limit should never be exceeded, except in the event of a sudden and catastrophic breakdown of a critical process control component.

Akers noted that values presented in the current U.S.P. (1116) (8) are target values (13). Given this designation, it is reasonable to consider these values to be *operational target levels*, rather than *product quality control limits*. There are several models for setting alert, action and fail limits, although many only establish alert and action limits (14) (other terminology may be used). Extending one current model (14), the alert limit might be considered to be the 95th percentile. Analysis and trending of actual data allow the calculation of this limit, as well as the 97th percentile for the action limit, and the 99th percentile as

the fail limit. Regardless of the model used initially to set limits, they should be based upon both historical data, and an evaluation of correlations between monitoring results and product quality. Data analysis should include a mechanism for evaluation and modification of the monitoring program and limits.

It is expected that results will fall within normally anticipated operating levels (8, 9) (Table 1) with 95% confidence, if randomness in critical environments and operations is sufficiently controlled. If data from successful PQ runs (when the process is demonstrated to be under control) do not meet this criterion, the monitoring methods may not measure a phenomenon that relates directly to process control, may not be sufficiently reproducible to provide useful information, or may have been incorrectly conducted. Every effort should be made to develop monitoring methods that comply with this performance expectation so that data will be useful.

Initial limits may be calculated and compared to results of any unsuccessful trials. These limits should eventually be adjusted based on historical data (see Fig. 1). When evaluating data to adjust limits, Wilson (14) noted, "Including data taken from a period of unusually high counts, where the process was out of control, will lead to inappropriately high alert/action limits."

Conduct of Sampling

Quality management and sampling personnel require both an in-depth understanding of the environmental sampling rationale, and a complete understanding of commonly available equipment, materials, sampling techniques, and development methods. Reporting forms should be carefully designed to convey all relevant information including identification of the technician, sample location (from a standardized sample map), date and time, media (including lot, expiration, and validation date), method, duration of sampling, and equipment (including calibration date and serial number). In addition, information such as the product batch, number and names of personnel, line throughput rate, number and nature of line interventions, and other available monitoring data such as room pressure and other engineering control status readings should be recorded. Any observed deviations from standard operating procedures (SOPs) should be noted and communicated to the individuals responsible for training and management of operative personnel. It is essential to repeat samples when such deviations occur in order to evaluate the impact they may have on results.

Sampling and laboratory personnel must be highly competent on both philosophical and functional levels, and

must develop and exercise *perfect* aseptic technique (13). A training program and operating procedures should be established defining all monitoring steps, including gowning, preparation of samplers, aseptic sampling techniques, sample recovery, handling and transport, and laboratory techniques for aseptic sample development. A laboratory QA program should assure that monitoring personnel conform to operating procedures and that technician skills are periodically tested and validated for high competence and flawless technique (13).

Sample Handling

Sampling, sample transport, and sample development should be conducted in a way that does not affect results. For example, if agar plates are improperly transported, condensate may form on the lid and drip onto the agar surface, redistributing microorganisms over the surface and around the edges of the plate, causing false readings. Agar plates should, therefore, be kept inverted and oriented horizontally during storage and transport. They should be handled gently, and transferred to the incubator as quickly as possible after exposure. With sieve impactors, false positives can usually be identified as colony forming units (CFUs) that fall outside the star pattern of jet indentations in the agar surface below the holes. Counts >20 CFUs may also be statistically corrected for increased accuracy by using the positive-hole correction table (15).

It is recommended that colony counts be made at several points in the incubation process, with separate tallies for bacterial and fungal colonies that tend to merge at a critical point during incubation, when fungal colonies may overgrow and obscure bacterial colonies. For this reason, any bacterial subcultures should be made prior to the onset of rapid fungal growth. Whenever possible, optical electronic colony counters with sufficient back-lighting and magnification to enhance contrast and enumeration should be employed to increase accuracy. In the presence of known or potentially high counts, the microscope enumeration method should be used to closely differentiate and count microcolonies in impact areas on sample plates following a short incubation period.

DEVELOPING A MONITORING PLAN

Site Selection

A critical site is a point at which the product is exposed to the environment, when something is added to the product

or product pathway, or a point at which unprotected product is manipulated. Any intervention into the process line increases the potential for contamination. (Examples of line interventions include the introduction, removal, or manipulation of materials and product, equipment adjustments, and sampling activities.) Particular attention should be given to these sites and events in the development of the monitoring plans (3).

Analysis of a videotape of repetitive prequalification should be studied for behavior and practices that may produce or harbor environmental contamination, leading to the refinement and optimization of work practices, and development of the formalized process to be instituted for the PQ validation run. The videotape may be used for identifying indicator sites, which should be incorporated into the monitoring plans, and intensively sampled during the validation run. These tapes should be retained and edited for both training and informational purposes.

For critical processes, it is important to select noninvasive sampling methods that have high collection efficiency for a broad range of organisms. To select the most suitable monitoring methods and equipment, the probable route of contamination for each critical site or process should be identified. For example, when the most likely route of potential contamination is touch, select surface sampling techniques for personnel barriers. When the most likely route is transfer from contaminated work surfaces, sampling of these surfaces is most useful. At sites where unprotected product is exposed to the environment, aerobiological monitoring is indicated, and, in unidirectional airflow, must be carried out isokinetically and isoaxially^b in the manner of nonviable particle-count testing. Some processing steps may require multiple sampling methods.

Controlled support areas adjacent to critical areas are the essential interfaces in the transition from the general environment to the aseptic processing core. These areas should be adequately pressurized, facilitating a gradient flow of contaminants from cleaner to dirtier areas (10). Controlled staging, support, material storage areas, and work practices should be examined and indicator sites identified. Controlled areas should be maintained and monitored in accordance with guidelines and industry standards (Table 1).

^bIsoaxial: A condition of sampling in which the direction (axis) of the airflow into the sampling probe inlet is the same as that of the unidirectional airflow being sampled (7). Isokinetic sampling: The condition of isoaxial sampling in which the mean velocity of the air entering the probe inlet is the same as that of the unidirectional airflow being sampled (7)

Personnel, Equipment, and Facility

Validation and monitoring of a process are normally divided into three main areas of concern: personnel, equipment, and facility.

The human factor is the greatest potential variable in any process. Uncontrolled variation in personal health and hygiene, barrier techniques, and aseptic technique may cause wide variation in contamination of controlled support areas and process materials during staging and preparation, as well as adventitious contamination of the aseptic process core and product. A suitable aseptic process, defining appropriate and standardized personal hygiene expectations, scrubbing and preparation techniques, barrier techniques, and operator techniques should be developed and challenged intensively during the PQ exercise. Personnel should periodically take both written and media-fill skill tests (3).

Ongoing monitoring for compliance with pertinent SOPs should then be conducted. Sampling of personnel barriers, such as gloves, shoe covers, hair cover, and gowns facilitates detection of potential “fallout” contaminants shed from personnel for evaluation of both barrier and aseptic techniques. This information may be useful in establishing required garb-change intervals, based upon measured garb-penetration times by endogenous contaminants. All accumulated data should be used periodically to develop a facility trend analysis which, in turn, modifies training and work practices as necessary.

All equipment used in controlled manufacturing or compounding processes should be designed, staged, and sanitized in a manner that facilitates unvarying routine operation, with minimal human intervention. This reduces the potential for random cross-contamination by operative personnel. Improperly sanitized or sterilized equipment or components are also a possible source of contamination.^c Monitoring of representative surfaces of process equipment should be carried out and documented.

Facility sampling should be carried out under both as-built and at-rest (7) conditions during initial installation qualification (IQ) and operational qualification (OQ) of the facility, in order to baseline and “bracket” performance of the engineering controls, and to identify the normal background flora present in the manufacturing environment. Sampling should then be conducted in-process

under operational conditions (7) during the PQ, to identify the impact of the process and personnel on the product and environment. It is important to monitor the validation process during all shifts and throughout the shift. Sites should be standardized and selected by statistical models or grid profiling (16), based upon testing and monitoring requirements appropriate to the specific process (Table 1).

Surface sampling is useful in verifying the effectiveness of housekeeping and sanitizing procedures. It may also provide an alert to poor materials preparation prior to introduction into the controlled environment, or to lapses in personnel technique or barrier use. Aerobiologic sampling is most useful when conducted in conjunction with a complete program for testing of the engineering control system (10). Recommended tests include the following:

1. Facility pressurization, which should be routinely monitored at recommended intervals (20);
2. High efficiency particulate air (HEPA) filter velocity and uniformity testing for laminar airflow (21), and volume in cubic ft/min (CFM) for conventional flow, including a determination of room installation air changes (10);
3. HEPA filter leak-integrity testing (18);
4. Nonviable particulate cleanliness testing (7); and
5. Smoke-tracer visualization for establishing the integrity of unidirectional-flow areas (10).

Periodic retesting of challenges 1–4 is required by some regulatory groups, with the interval determined by the nature of the process and product in a given area (17). Repeating Test 5 may be useful in evaluating failures and can be an extremely valuable training tool. Concomitant particle count testing may be useful in identifying contamination indicator sites.

Monitoring of laminar airflow workstations (LAFWs) requires a complete understanding of HEPA filtration system performance, and is frequently conducted in ways that do not yield useful information. When properly validated in accordance with Federal Standard 209b [Appendix A, para. 40 and 50^a], LAFWs provide air at the entrance plane which is far cleaner than Class 100 (10). Testing to this cleanliness level would permit particulate contamination levels two orders of magnitude greater than during filter OQ validation testing. More important, the use of any apparatus that samples discrete locations in a unidirectional slip stream is unlikely to detect filter leakage because isoaxial and isokinetic sampling at the exact point of leakage would be required. Therefore, placement of a sampling probe upstream from the product is unreliable and an unnecessary threat to sterility. The only practical, in-process use of these

^cThe sterilization process for any equipment or supplies that are sterilized prior to introduction into the controlled environment must be validated, with sterilization records and verifications included in all product batch histories. Validation of sterilization equipment, alone, is not sufficient to assure sterility. Because the types of materials being sterilized, and the arrangement of articles within the sterilizer can effect results, standardized load configurations must be developed and validated

instruments is to detect shifts in the amount of particles and microbiologic contaminants caused by the process at some point adjacent to or downstream from the product. Such a shift might signal a lapse in personnel technique, barrier use, or prestaging material preparation, or be caused by HEPA filter loading, which reduces airflow velocity.

Avoiding Sampling-Induced False Positives

Line interventions for sampling purposes must be balanced carefully against the total number of interventions necessary for production purposes. Sampling should present the minimum risk of contamination, which is theoretically the same for every line intervention. Because sampling-induced positives should not exceed 10% of total positives ($10^{-1}N_p$) (17), the number of sampling interventions should be significantly lower than the number of production line interventions. In isolators or other isolated critical processes, where no line interventions occur during production, not more than one, carefully controlled, aseptic sampling intervention is recommended.

Surface sampling the exterior of finished products, as indicator sites, assembled from purportedly sterile components as they exit the process while still under aseptic conditions, may be a more efficacious method of estimating microbiologic contamination potential than invading the critical production site. This method allows sampling the most critical site adjacent to the product, and more sites may be noninvasively sampled over a longer interval. In addition, this method may substantially reduce the incidence of sampling-induced contamination.

Monitoring Frequency

The frequency of monitoring should be determined by the maximum interval acceptable for an over-limit condition to remain undetected (19). This depends upon the critical nature of the process within the monitored area. In general, the minimum frequency should be consistent with applicable regulatory guidelines (Table 1). Although it has been suggested that monitoring frequency can be reduced if no over-limit condition is detected within a predetermined number of monitoring cycles, this practice is inconsistent with basic monitoring rationale. Monitoring is conducted to detect a breakdown in process controls, which may occur at any time. Even if no control component has failed for a prolonged period, it must be assumed that a failure will occur eventually and must be detected within the predetermined interval. In addition, lack of over-limit test results may be due to the fact that

monitoring method(s) are not sufficiently sensitive, or that limits are too high.

EVALUATION OF THE MONITORING PLAN AND LIMITS

Most discussions of microbiologic monitoring recommend that the monitoring plan and limits be based on historical data, but offer little guidance on how this can be accomplished. Figure 1 provides a guide for evaluation and revision of the monitoring plan and limits. An in-depth evaluation may be triggered by over-limit results from monitoring (Entry Point 1) or by adverse product testing results without detection of any over-limit condition through routine monitoring (Entry Point 2).

Entry Point 1:

1. Conduct routine monitoring. A counter (*C*) is used for Step 11. $C = 0$ at the beginning of the routine monitoring program.
2. If the results do not exceed any limit, then continue routine monitoring.
3. If the results exceed any limit, then perform retesting in triplicate to verify the accuracy of results. Retest under the same conditions noted on the sampling form (i.e., same time of day, same location and operator, same type of production).
4. If triplicate retest results are not over-limit, it is assumed that the original over-limit result was due to a nonassignable cause (*NAC*). Determine the probable cause of the over-limit count (i.e., unusual activities noted on test documentation, sampling, lab error, etc.). A record of positive *NAC*s should be kept and analyzed to determine ways to improve affected processes and sampling procedures. Return to routine monitoring.
5. If results are over an alert limit, but not over the action limit, then enhance monitoring frequency for *X* cycles. (*X* is determined by the critical level of the area and process where the over-limit event occurred, but should provide an adequate interval to assure detection of a continued deterioration of process control.)
 - a. If the alert limit is not exceeded again within *X* cycles, then return to Step 4.
 - b. If the alert limit is exceeded but the action limit is not, then proceed to Step 10.
 - c. If the action limit is exceeded, then go to the corrective action plan (*CAP*) (5).
6. If results following the triplicate retesting are over the action limit, but not the fail limit, then go to the *CAP*.

7. If the results following the triplicate resting are over the fail limit, traditional QA protocols usually require that operations cease. However, the appropriate action taken should depend on the critical nature of the monitored step and other conditions. An alternative to operation shut down may be to segregate and hold the product for enhanced testing for adverse effect; go to the CAP.
8. If implementation of the CAP results in the determination of the cause of the over-limit condition, then correct the condition, and retest in triplicate to verify that the problem was corrected. If no cause was found, then proceed to Step 10.
9. If test results following corrective action are within limits, then return to routine monitoring.
10. If test results following corrective action are still over-limit, or if no cause of the over-limit condition can be identified, then evaluate the product for adverse effects.
11. If no adverse impact on product quality can be detected, add 1 to the counter (*C*). The result may indicate that limits are too low, but one event is not sufficient to support a decision to increase limits.
 - a. If $C = 3$, then the limits are too sensitive, and should be increased.
 - b. If $C < 3$, return to routine monitoring. Because the results are over-limit at this point, a repeat investigation of the cause of over-limit results will be triggered. Limits should be increased judiciously, and it is important to be thorough in attempting to resolve any cause of over-limit testing with reasonable certainty before increasing limits. For example, if the cause of the over-limit result is sampling mistakes or lab error, there will be no detectable cause in the production facility, the process or engineering control evaluations, and probably no adverse effect on product quality. This should not, however, be interpreted to mean that limits are too sensitive.
12. If product is adversely affected, and no cause can be detected following implementation of the CAP, the monitoring plan and/or the process should be redesigned and revalidated.

Entry Point 2:

13. If product quality is below limits, but monitoring data did not detect the shift, then reevaluate monitoring data using lower limits to determine whether or not the process shift could have been detected. If the data have been graphically represented, this should be

quite simple; increasing the amplitude of the graph may be useful.

14. If lower limits would have detected the shift, then lower the limits and institute the CAP.
15. If lower limits would not have detected the shift, then evaluate the cause of the failure, and develop a new sampling strategy for the key step(s) where failure occurred. Institute the CAP and verify that corrective actions taken were effective in improving product quality.
16. If product quality improves, then add the new sampling method to the routine monitoring program.
17. If it does not, return to Step 12.

SELECTION OF MONITORING METHODS, MATERIALS, AND EQUIPMENT

Effective microbiologic monitoring of controlled processes usually includes sampling of process air for aerobiologic contamination, and facility, equipment, and operative personnel barriers for surface contamination. Equipment and methods used in monitoring procedures must be carefully considered for attributes and limitations and must be matched to sampling objectives to ensure that methods and techniques are noninvasive, and to facilitate development of well-organized sampling plans, techniques, data, and data trending analysis.

Surface Sampling

Surface sampling may be performed at the conclusion of critical operations to minimize disruption of these processes (8) and prior to sanitizing procedures (20) to estimate cumulative, inprocess contaminant burden (4). In addition, presanitization surface sampling is beneficial in detecting operations-induced bioburden and cross-contamination between environmental and equipment surfaces. Postsanitization surface sampling is useful for evaluating sanitizing methods and in retrieving sanitization-resistant isolates for identification and trend analysis in demonstrating sanitizing compound efficacy. The two most common types of surface sampling are swab-sampling, and surface contact sampling.

Swab-sampling

Swab-sampling is normally used for flat or irregular, nonabsorbent surfaces with qualitative development by inoculation of the swab matrix directly into nutrient broth, observed for growth/no growth. Quantitative development is also possible (5). The main advantage of the swab

method is accessibility to difficult-to-reach equipment surfaces and areas of the production environment. Limitations are excessive time consumption, increased potential for adventitious contamination due to the cumbersome nature of the procedure, and failure of enumeration processes to correlate to full recovery of organisms.

Contact plates

Surface contact plates are normally used for sampling flat or irregular, absorbent or nonabsorbent surfaces. The surface contact plate consists of a clear plastic base housing a convex protrusion of nutrient agar with a plastic cover. Sampling is accomplished by pressing the agar against the site.

The covered plate is then incubated for development, and the CFUs per square centimeter enumerated (21). Advantages of surface contact plates are reproducibility, speed, simplicity of collection mechanism, and minimized potential for adventitious contamination; collection and correlation to recovery of organisms are superior to swab-sampling.

Aerobiologic Sampling

Aerobiologic sampling is conducted in critical and controlled areas to detect airborne viable contaminants present during manufacturing operations. Aerobiologic sampling procedures, frequency, and limits should be established based upon environmental conditions required to maintain product quality, and established for each processing step (4) (Table 1). Aerobiologic sampling employs two basic methodologies:

1. The gravity settle plate, which provides passive measurement of microorganisms likely to deposit by sedimentation at critical and controlled sites within a given period, and
2. The volumetric air sampler, which provides active measurement of viable contaminants by mechanical aspiration and dynamic inoculation of process air.

Gravity settle plates

The gravity settle plate measures microorganisms settling from the air onto a known surface area in a known time. Settle plates may be positioned within the critical area at indicator sites where the product may become exposed to airborne contamination, and in controlled areas at locations identified as likely sources or areas of "fallout" aerobiologic contamination. Settle plates are not appropriate aerobiologic sampling method for monitoring the efficiency of unidirectional (laminar)

airflow or other air-cleaning devices. This is based upon studies (22, 23), and the general assumption that "... the settling velocity of contaminants (in unidirectional airflow) is negligible, which implies that gravitation plays an inferior role. With the assumption of a constant value of the diffusion coefficient, the diffusion equation in a velocity field within rectangular coordinates becomes

$$\frac{\partial c}{\partial t} + v_x \frac{\partial c}{\partial x} + v_y \frac{\partial c}{\partial y} + v_z \frac{\partial c}{\partial z} = D \left(\frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial y^2} + \frac{\partial^2 c}{\partial z^2} \right) \quad (1)$$

where c is concentration: v_x , v_y , v_z are velocities in the x , y , and z directions; and D is diffusion coefficient.

This gives the simplest possible mathematical model which describes a system with regard to transport of contaminants emitted in a source of an arbitrary position..." (23), demonstrating that particle dispersion in undisturbed streamlines is primarily a function of streamline uniformity and velocity. Disruptions of the parallel (laminar) airflow streamlines caused by equipment, personnel movement, and product result in turbulent flow, creating small and temporary vortices and eddies. It is only turbulent diffusion within the vortex that causes removal of entrained contaminants (23). Therefore settle plates, strategically placed, are reported to provide a superior method of predicting potential product contamination by mimicking the deposition of microbe-carrying particles (MCPs) into or onto the product^d (24). They are inexpensive, may be used to continuously monitor the entire production interval, are less invasive of aseptic operations, and may usually be placed closer to exposed products than volumetric air samplers.

Settle plates cannot be used for quantitative measurement of airborne microorganisms because the sample volume of sedimentation air samples cannot be measured. Air turbulence around an open plate may also effect collection results, and smaller particles may not settle at all (22). In addition, extended exposure times may result in

^dRegardless of placement of an aerobiological sampler in a laminar airflow work zone, it can at best measure the effect of the process at some point downstream from the product. For example, the mouth of a flask may be situated in "first air" issuing from the HEPA filter, while air impinging on the surface of a plate adjacent to it will be affected by disruptions of the airstream caused by the flask. Contamination found on the plate then results from a different set of conditions than those to which the product is subjected and does not exactly parallel the product contamination mechanism. Only a media-fill process simulation can fulfill this function. Aerobiologic sampling immediately downstream of the critical orifice can, however, detect downward shifts in the overall cleanliness of the critical process air, which in turn may indicate increased contamination potential near the product

some desiccation of the nutrient agar, resulting in poor microbial growth (25).

Volumetric air samplers

As an active sampling method, the volumetric air sampler aspirates a known volume of process air, capturing microorganisms into or onto a nutrient agar medium, a liquid, or a filter. Microorganisms are developed and quantified as an estimate of CFUs present in the sampled environment per cubic foot of air (or other volumetric measurement) (4). The quantitative principles of volumetric (active) air sampling may be expressed by

$$S(R_t)C = R_f \quad (2)$$

where S is source intensity, R_t is transport rate, C is correction factor, and R_f is failure rate.

Volumetric air sampling is accomplished by a number of different methodologies, including impingement, impaction through single or multiple orifices, centrifugal impaction, and filtration. Each method has inherent advantages and disadvantages that affect the value of the data collected relative to the specific application. Table 2 presents a comparison of popular samplers based upon relative cost, difficulty of use, appropriate applications, and other factors.

Impingement: In an impinger, a known volume of air is drawn through fluid in a glass vessel (20, 30). Particles separate from the airstream by impinging at the flask bottom, where they are stopped and retained by the liquid as the air continues to flow out through the pump system. High air velocities passing through the impinger effectively break up bacterial/particulate aggregates, resulting in microbial counts, which more closely reflect the actual number of microorganisms, leading to recommendations that impingers be used as the standard reference method for monitoring aerobiologic contamination (26, 28). However, impingers may require the addition of antifoam agents and replacement of fluid, due to agitation and evaporation loss during longer sampling procedures.

These additional steps increase the possibility of adventitious contamination. It has been demonstrated that the sampling efficiency of an impinger is dependent upon both system design and the particle sizes being sampled (29). Accuracy and reproducibility of results have been reported to be difficult, and particles of $<5.0 \mu\text{m}$ have been demonstrated to pass through the impingers tested (30).

Impaction: In slit-to-agar (STA) or sieve impactors, a known volume of air is aspirated through a single orifice

(STA), or multiple orifices (sieve), and viable particles, due to their inertia, are forced out of inlet airflow streamlines and impacted onto perpendicular, target nutrient agars as the streamlines abruptly change direction to bypass the target stage. In the centrifugal impaction sampler, high centrifugal forces created by “spinning” air through an impeller turbine at sufficient velocities to cause separation of microorganisms from sample air streamlines result in their impaction onto a nutrient agar strip placed at the inner periphery of the sampling chamber, parallel to the inlet airflow axis.

Sieve impactors are available in single-stage or multistage designs that facilitate both enumeration and sizing of aerobiological contaminants. As the sample air transits the device, sample velocities increase at each stage, resulting in gradient deposition and accurate sizing of microorganisms of smaller diameters and lower mass. Microorganisms aspirated by sieve samplers through a matrix of multiple-inlet orifices impact directly onto an agar medium for development from a single agar plate for each vertically stacked stage, with no further subculture steps required for enumeration. Advantages of sieve samplers are generally high particle deposition rates, the ability to size particles and vary sampling time and volume, and superior collection efficiencies when compared to other methods of aerobiological testing. Single- and six-stage configurations have been reported to be two of the three sampling methods of choice (27).

Use of STA samplers in isolators and critical process zones should be accomplished using a sterile sampling hose and probe, facilitating remote location of the sampler in a noncritical area. In monitoring a unidirectional slipstream, this hose/probe configuration should be both isoaxially oriented, and isokinetic^b, in order to minimize disruption of the slipstream. Advantages of the STA include the ability to revolve the plate at varying rates so that the samples may demonstrate changes in aerobiological concentrations directly over time, and the ability to obtain multiple samples with a single petri dish (31). STA samplers have historically been the standard against which other air samplers are assessed (17, 32). Agar plates are easily removed from the sampler for development, with contamination enumerated as CFUs per unit of air sampled.

The STA is reported to be both unsuitable for use in the presence of high concentrations of organisms (33) and cumbersome to use (17). In addition, it has been demonstrated that a significantly higher percentage of particles sized $0.5\text{--}0.8 \mu\text{m}$, and a significantly lower percentage of particles sized $3.0\text{--}25.0 \mu\text{m}$, were present in sample air, which had passed through the slit of an STA,

than were found in ambient air (34). This was attributed to fragmentation of larger particles following passage through the slit of the STA.^c

Due to dehydration of the agar reported to occur over long sampling periods, continuous sampling exceeding 30 min using an impaction sampler is not recommended. Areas of loss have been reported for sieve samplers (40), including *inlet loss* (the effect of cross-wind at the sample inlet point), *interstage loss* (deposition of particles on internal surfaces other than the impaction agar), and *particle re-entrainment* (particles reintroduced into the airstream due to particle “bounce,” resulting from dehydration of the impaction agar).

Advantages of the centrifugal sampler are the capability of sampling large amounts of air (40 L/min) in a short time; it is quiet, lightweight, self-contained, and does not require cumbersome air pumps or external power for operation. Centrifugal samplers provide a good indication of environmental isolates (17).

Centrifugal sampling cannot be carried out isokinetically (23), and the accuracy of results is dependent upon the sizes of the particles being sampled. Since particulate sizes in the air volume being sampled are not routinely determined, the validity of the centrifugal sampler as a quantitative device has been called into question (36), especially for quantification of small particles (27, 37). Another recent study indicates that centrifugal sampling causes air to move in a turbulent, mixing manner, introducing heavily disturbed airflow patterns around the sampler which may, in turn, impart disturbances to any unidirectional airflow patterns being sampled (23). Reaspiration of sampled air is also a problem with earlier designs, creating difficulty in discriminating between incoming and outgoing airstreams, which is necessary to quantify microorganisms (38). Proprietary agar medium strips are specially designed and unique to this system, and require careful technique to insert and remove aseptically.

Membrane filtration: Membrane filtration (MF) sampling is accomplished by capturing aerobiological contamination as it passes through a cellulose membrane filter (CMF) or gelatin membrane filter (GMF). The mechanisms of MF particle removal are inertial impaction, diffusional interception, and direct interception. Following collection, the GMF may be plated aseptically onto an agar petri dish to dissolve, allowing microorganisms to grow directly on the nutrient medium. Dissolution of the membrane into a sterile solution is also possible (31).

^cInterestingly, this attribute was reported by investigators to be an advantage of the all-glass Impinger (31, 32).

While MF sampling has been demonstrated to be the most effective means of retaining aerobiological contamination, CMF sampling exhibits a lower recovery rate than an impinger when tested against stress-sensitive microorganisms, such as *Serratia marcescens* (39) or *Escherichia coli* (27) due to desiccation on the CMF surface. Studies have indicated that gelatin foam filters incorporated into GMF gave significantly higher recovery rates than CMF over the same sampling period (40, 41). Recent comparisons of sampling systems indicate that GMF is equally as effective as the STA sampler, irrespective of particle size, and is significantly more effective than centrifugal sampling in the collection of microorganisms with sizes <5.0 μm (31). A recent study comparing the GMF system with centrifugal, sieve, and STA systems in sampling the unidirectional airflow slipstream in the presence of visual tracers indicates the GMF sampler to be the only sampling method capable of isokinetic and isoaxial sampling with no visual disturbance to the laminar airflow pattern (31). However, in this study, the STA was tested without the remote hose-isokinetic probe device.

Limitations of the GMF are an additional aseptic subculture step, which increases the probability of adventitious contamination, and a proprietary membrane filter, which results in a per-sample cost currently exceeding 12 times that of the one-stage sieve, SAS, STA, SMA, and glass impinger systems, and four times that of the centrifugal sampler.

Growth Media

Growth and collection media used in microbiologic monitoring should be selected on the basis of the target organisms, areas and surfaces sampled, and inhibitory residues that may remain on the sampled surfaces. Media commonly used for environmental monitoring are listed in Table 3. Under certain circumstances (e.g., when obligate anaerobes are recovered from the product), additional, specific media and methods should be selected by a qualified microbiologist (17).

Comparison of Aerobiologic Samplers

The different characteristics and operating principles of aerobiological samplers do not facilitate direct and simple comparisons. The user should, therefore, carefully evaluate the numerous advantages and disadvantages of each method in selecting a sampler for the intended application (42) (Table 2). Two studies that provide basic comparisons of aerobiological sampling systems may offer useful information:

Table 3 Media commonly used for environmental monitoring

Medium	Selective for	Sample application
Tryptic soy agar (TSA) ^{a,b}	Aerobes and facultative anaerobes	Air and surface
Lethen agar ^c	Aerobes and facultative anaerobes	Surface
DE neutralizing agar ^d	Aerobes and facultative anaerobes	Surface
Sabouraud dextrose agar	Yeast and molds	Air and surface
Rose bengal agar	Yeast and molds	Air and surface
Buffer solution ^e		Surface

^aTryptic soy agar is also known as soybean casein digest agar.

^bUnmodified general purpose medium use for culturing bacteria and/or fungi.

^cContains additives used to neutralize residuals of halogen-based disinfectants, such as sodium hypochlorite (bleach).

^dContains additives used to neutralize residuals of halogen and quaternary ammonium chloride-based disinfectants.

^eSamples collected using sterile swabs and buffer solution must be transferred to media for culturing and enumeration.

A study comparing eight bioaerosol samplers was carried out by Jensen et al. in 1992 (27). Results indicated that the Andersen 6-STG, I-STG, and Ace Glass AGI 30 samplers were the samplers of choice for recovering aerosols of free bacteria (i.e., mostly single cells of *E. coli* and *B. subtilis*, $d_{ae} \geq 2 \mu\text{m}$) under the controlled conditions of the study (43). Another study, comparing seven samplers commonly used in controlled environments, was conducted by Ljungqvist and Reinmüller in 1998 (44). This study indicated widely varying results for the impaction samplers tested. The limited number of parallel tests performed prevented an evaluation of comparative collection efficiencies based upon statistical considerations. The salient recommendations of this study are that results should be seen more "... as an indication of a [contamination] level and not be taken as a true absolute value," and that aerobiological samplers be selected carefully, based on practicalities of using different types for different locations or situations. Furthermore, this study recommends the simultaneous use of a discrete

particle counter (DPC) to measure the total number of airborne particles present in the area sampled.^f

ANALYSIS AND INTERPRETATION OF MONITORING RESULTS

Effective interpretation of data from microbiologic monitoring of the environment can be the most difficult aspect of the monitoring process. Several factors complicate this process, including the inherently nonrandom distribution of most microbial contamination events, errors in sample handling, variation of sampling technique from one monitoring event to the next, and seasonal shifts in the type and level of contaminants likely to be present in the general environment.

The purpose of statistical evaluation of sample data is to extrapolate from a collection of individual events (e.g., 30 min of process time) to the entire population of events (e.g.,

^fBecause it is impossible to derive instantaneous results from microbiologic testing, the authors agree that such data should, where possible, be correlated with a DPC as an instantaneous data source, in developing useful historical data. Although "... no universal relationship has been established between the total concentration of airborne particles and the concentration of viable airborne particles..." (7), such a correlation may be possible under controlled operational conditions within a specific area or facility (determined by Ljungqvist and Reinmüller in two facilities) to be approximately 10^{-4} (10,000:1). Such a correlation would facilitate a "viability index" as a rational means of correlating shifts in instantly available particle count values with probable corresponding shifts in aerobiological contamination. This technique would be very useful in the instantaneous identification of contamination indicator sites. Similar correlations have been established on a facility-specific basis by the Lab Safety Corp. during the course of regular, periodic aerobiological sampling of three bone marrow transplant

complexes over a period of several years. In all cases, a correlation of the total population of aerobiological contaminants to instantaneous DPC data (termed the "viability index") was used to trace the distribution and probable presence of the life-threatening organism *A. niger* in immunocompromised patient populations. Although it was found that in these highly controlled facilities (e.g., Class 1000 or better) the correlation was one to two orders of magnitude higher than that described by Ljungqvist and Reinmüller (42,44), the correlations were consistent, allowing facility managers to reliably detect possible life-threatening deteriorations of the critical patient environment through the use of instantaneous DPC data as an aerobiological contamination indicator. The data analyzed indicate that aerobiological contaminants appear to increase in proportion to nonviable contaminants as the cleanliness of a facility increases. This is probably due to the fact that, as general environmental contamination is eliminated, human activity becomes the principal source of contamination.

Fig. 2 Out-of-control pattern recognition. (a) Change or jump in level; (b) Trend or steady change in level; (c) Two populations; (d) Recurring cycles. (Chart courtesy of Prentice Hall, Inc., Upper Saddle River, NJ.)

8-h shift). Because microbial monitoring data usually measure the impact of human activity, which is not reproducible exactly from one event to the next, results usually do not fit standard statistical models for normal distributions. In spite of this limitation, it is necessary to summarize the data for comparison to limits. The best statistical methods of evaluation are determined by the nature of the data (14). Wilson suggests that microbial monitoring data histograms generally resemble Poisson or negative exponential distributions (14), whereas Akers points out that Poisson distributions may only be appropriate for systems with minimal human intervention (12). The formula for the Poisson distribution (45) is given by

$$P(C) = \frac{(np_0)^C}{C!} e^{-np_0} \quad (3)$$

where C is individual sample count, np_0 is average count, and $e = 2.718281$.

Trend analysis of results at individual sample locations may be more useful than statistical analysis of data summaries because each sampling location probably reflects a unique situation. Nontraditional groupings of data may also be valuable. For example, grouping all locations where a specific activity was noted on the sample collection form, grouping all data collected during a specific time frame (i.e., just after lunch, or near the end of a production cycle), or grouping all data for each operator may reveal specific problem areas.

The example control charts presented by Besterfield in Fig. 2 demonstrate four major types of out-of-control patterns (45). A fifth pattern is due to mistakes, which will usually show up as isolated, out-of-control points. All apply equally to production and sampling operations. All patterns may be observed on both range (R) charts and standard (or reference) process average charts, but are usually more common to charts.

Likely causes for each type of pattern can be identified, and a checklist of assignable causes applicable to the particular process should be developed through cause and effect (C&E) analysis (45). Examples of likely causes for these patterns are:

- A change or jump in pattern caused by an inexperienced operator, a change in raw materials, or a failure of an equipment part;
- A trend or steady change in level due to a gradual change in the production environment, a gradual change in equipment performance (e.g. HEPA filter loading), or a gradual tendency toward lax observation of SOPs;
- Two populations may be due to more than one process line or piece of critical equipment on the same chart, more than one operator on the same chart, or different samplers or sampling techniques; and
- Recurring cycles may be caused by periodic operator rotation, operator fatigue and rejuvenation cycles, sanitizing and cleaning cycles, and seasonal shifts.

Recurring cycles may be missed if sampling intervals happen to coincide with the cycle frequency, in which case only the low or high range of the cycle may be detected. Out-of-limit trends near the lower limits of the R chart represent superior performance and should be analyzed to identify methods of maintaining these process levels (45). Whatever statistical methods are employed for summarizing data, graphic representations, such as histograms and process control charts can be extremely useful for detecting trends or cyclic patterns in test results.

There are two types of over-limit results: *Random* results are due to chance (unassignable) causes, whereas *nonrandom* results are due to assignable causes. For a controlled process and facility, the objective is to differentiate between individual data points that are assignable and those that are not. If the individual over-limit event is not repeated during subsequent, multiple retests, it is not assignable and does not represent a deteriorating trend. All statistical evaluation methods include mechanisms for “discarding” spurious data. There is, however, a cause for any unassignable result, and efforts should be made to identify and understand it. All data have meaning, and may be useful for improving the process or testing procedures.

Speciation

Speciation of microorganisms is indicated when product testing results detect the presence of a specific organism, when evaluating the efficacy of sanitizing compounds and routines, and when monitoring results trigger the corrective action plan. Speciation should be carried out and analyzed by a qualified microbiologist familiar with the sampling equipment, sampling methods employed, and the origins of organisms commonly found in cleanrooms (17,46). Speciation should also be conducted periodically to identify isolates normally recovered when the process is operating within limits, and may be useful in identifying the probable cause(s) of any out-of-limit condition. During the initial phase of the corrective action plan, an analysis of probable contamination sources and routes should be made for all organisms identified (17). Information obtained by speciation may immediately indicate the most likely source. This information may also indicate less common contamination sources, such as perverted cleaning solutions.

Periodic re-evaluation of the monitoring plan should be carried out, and seasonal effects considered in trend analysis. Many sampling methods do not collect all organisms with equal efficiency, and organisms likely to be present may vary seasonally. Any seasonal shift (up or down) should be investigated by speciation, and sampler correction factors for the predominant organisms applied.

CORRECTIVE ACTION PLAN

The CAP should clearly define and document

1. The method of data analysis;
2. Alert, action, and fail limits;

3. Corrective actions to be employed in the event of detection of a deteriorating trend or an over-limit condition; and
4. A means of confirming the effectiveness of corrective action(s).

A verified trend above the action or fail limit should immediately trigger implementation of the CAP. Because human activity is the most likely source of process control failure, the investigative process normally begins with personnel, and proceeds through the various possible causes from most to least likely. An exception to this general plan is verification of room pressurization, which is a primary indication of engineering control equipment efficiency. Although routine monitoring of pressurization should detect any out-of-limit results, the simplicity of verifying proper pressurization suggests this as a first step.

In general, the cause of any deterioration in process or environmental control can be traced to one of three principle systems: a) personnel controls, b) process controls, or c) facility (engineering) controls. Increases in detected airborne microbiologic contamination levels may result from any of several conditions, and a simple set of logical challenges can be applied to the data to determine the most likely cause.

Challenge 1, *Is the increase real and reproducible?* If it is not reproducible, it may be due to sampling error, or NACs. If it is reproducible, it may be due to an actual increase in levels, or due to enhanced collection efficiency, due to changes in methods, materials, or seasonal or other shifts in the kinds of contaminants present (different organisms have different sampling efficiencies).; Challenge 2, *If the increase is real, is it due to an increase in source intensity, or to a decrease in the ability of engineering controls to maintain a clean air supply?* The easiest way to differentiate between these possibilities is to examine particle count data. There are several possible combinations of test results, each indicating a different cause for increased airborne contamination: a) If particle counts taken under operational conditions have not risen, but airborne microbiologic contamination has, it is most likely due to a breakdown in personnel discipline and/or gowning procedures. b) If operational particle counts have risen, but at-rest counts have not, it is again likely that the cause of elevated microbial contamination is personnel activity and that it represents an increase in source intensity (when human activity is eliminated, engineering controls are able to produce the same conditions that were present during the OQ validation phase). c) If at-rest particle counts have risen, the increase is probably due to a decrease in the efficiency of the engineering controls.

Similar logical tests can be applied to increases in surface contamination levels, which may be due to increases in source intensity, or decreases in the efficiency of barrier controls or cleaning and sanitizing procedures. Flow charts illustrating the logical evaluation of data, and investigation of out-of-limit results are useful as starting points in the development of corrective action plans (5).

MICROBIAL CONTROL OF PHARMACEUTICALS

Nigel A. Halls

GlaxoSmithKline Global Manufacturing and Supply, Uxbridge, United Kingdom

INTRODUCTION

Pharmaceutically active products (drug products) are expected to be efficacious, however; the presence of microorganisms in these products may have adverse effects on their efficacy. The severity of the effects that microorganisms may have on any particular drug product is a function of the nature of the product, its intended use, and the nature of the microorganism concerned. At one end of the spectrum, microbial contamination of a sterile parenteral product may, on injection into a debilitated patient, result in fatality; at the other, patients may refuse to begin or continue a course of medication because of aromas, off-flavors, or discolorations of microbial origin. In either situation, or in any related situation, the presence of microorganisms ought to be avoided in drug products.

Microbiological standards for drug products are published in the pharmacopoeias and/or are required by regulatory agencies for their registration. Generally, these standards are concerned with the protection of the public from infection by limiting the numbers and types of microorganisms to levels that are unlikely to be harmful. In addition to standards applying to the products themselves, there are also microbiological standards applying to the conditions under which drug products are allowed to be manufactured. These manufacturing standards (Good Manufacturing Practices, or GMPs) are intended to ensure that finished product standards are being attained consistently.

Microbial control of pharmaceuticals is primarily concerned with minimizing the opportunities for drug products to be contaminated by microorganisms. It is secondarily concerned with minimizing the potential for any microorganisms that may have contaminated drug products to increase to levels that may risk the efficacy of the product. The testing of product samples for compliance with microbiological standards is only one small part of this. By and large, microbiological test methods are product-destructive and, as a consequence, it is unusual to find valid statistical sampling and testing being done at batch release. Finished product testing is at best confirmatory and in some cases may be dispensed with when manufacturing controls ensure that products are

highly unlikely to become microbiologically contaminated (parametric release in its broadest sense).

Minimizing the risk of microbiological contamination of drug products is assured by the application of microbiological and physical standards and controls to starting materials, product-contact packaging components, manufacturing facilities, manufacturing processes, and equipment. By and large, these assurances are obtained by applying controls that protect materials, equipment, and processes from sources of microbiological contamination. In recognition of the frailty of protective measures in all but the most extreme circumstances, microbiological contaminants are also routinely controlled by removal, inactivation, or destruction.

The microbiological standards applying to drug products are expected to be maintained until time of use by the patient (or healthcare professional) and throughout their shelf-lives. This presents two areas of concern relevant to microbiological control: first, that the product should be protected (usually by its packaging) from additional contamination after release to market, and second, that the product should be formulated to prevent proliferation of any microorganisms that may have been present at tolerable levels at the time of release.

Different types and levels of microbial control are applicable to different types of products. The single major division is between sterile and nonsterile products.

MICROBIAL CONTROL OF STERILE PRODUCTS

Sterility is defined as the total absence of all viable life forms. Parenteral products and ophthalmic products are expected to be sterile. Parenteral products must be sterile because their route of administration overrides the body's external physical barriers to infection. Ophthalmic products must be sterile because eye damage is often irreparable. No distinction can be made between microorganisms that are known to be specific causative agents of disease and those that are not. Any microorganism may be opportunistically pathogenic if administered

parenterally or if applied to susceptible tissues (the transparent parts of the eye have a particularly poor blood supply and, therefore, a less sensitive immunological response than do other parts of the body) or to debilitated or immunocompromised patients.

Sterility, the Sterility Test, and Sterility Assurance

Sterility has an absolute definition (absence of ALL viable life forms). As with all absolutes, it is difficult, if not impossible, to prove.

Sterility tests

The pharmacopoeial standard applying to sterile products is that they must be capable of passing a Test for Sterility. A Test for Sterility is described in *U.S. Pharmacopeia* (USP) under Section 71 and in the *European Pharmacopoeia* (PhEur) under Section 2.6.1. These were “harmonized” along with the *Japanese Pharmacopoeia* and the requirements of the Australian Therapeutic Goods Administration in 1999, but they still have some minor differences in detail.

The Test for Sterility relies on the detection of viable microorganisms within a sample that is directly or indirectly inoculated into broad-spectrum microbiological recovery media. Detectable microbial growth is confirmation of nonsterility, whereas sterility can be assumed from the absence of growth. In other words, the Test assumes sterility unless nonsterility can be demonstrated. The Test for Sterility is really a test for nonsterility, and even within that redefinition of its terms of reference, its indication is limited to those microorganisms capable of producing discernible growth under the specified test conditions. Many microorganisms are not recoverable under these conditions.

When the Test for Sterility first appeared in the USP and in the *British Pharmacopoeia* (BP) in the 1930s, it was described in the same terms as any other pharmacopoeial test method; that is, as a method whereby a microbiologist could determine whether a single article presented for analysis was sterile.

There was no indication in the pharmacopoeias until 1955 in the USP and until 1968 in the BP that the results of the Test should be or could be extended to apply to batches of product required to be certified as sterile. The USP initially required 10 units to be tested from each batch of autoclaved products and 20 units from each batch of other sterile products, the BP required 20 units. In the current pharmacopoeias, the sample size for the Test for Sterility is 20 units in all but a few exceptional circumstances.

However, with such a small sample size, successful results (no growth inferring with sterility or “passing” the Test for Sterility) provide little assurance that there is not a significant proportion of contaminated units in the batch. This has been recognized and debated for many years, even before the pharmacopoeial requirements were first published. In 1949, Knudsen (1) pointed out that when using a sample size of 20 units, batches containing 5% contaminated units would be “passed” as sterile on 35 of every 100 occasions. Brewer (2) elaborated further on the statistical limitations of sterility testing by showing that sample sizes of 20, 50, and even 100 units are hardly better than sample sizes of 10 units for detecting contamination in batches of product containing 0.1% contaminated units. The pharmacopoeial sampling requirements for the Test for Sterility are a compromise; they have been known to be, and shown to be, statistically unsound for decades. They are a compromise between the fact that the Test is destructive to the units sampled and the self-evident requirement for a very high level of assurance that batches of supposedly sterile product do not contain nonsterile units.

In practical terms a “pass” in the Test for Sterility should not be perceived to be of any more significance than any other successful measure of compliance with microbiological or physical standards or controls applicable to the manufacture of sterile products. A “pass” in the Test for Sterility must not be allowed to overrule any failure to comply with other environmental or control standard(s) because it is quite possible to “pass” the Test and still have a significant number of nonsterile units in the batch. On the other hand, a “failed” Test for Sterility is likely to be a good indicator of a genuine problem that has not been disclosed by some other microbiological or physical means.

Methods for sterility testing

The Test for Sterility may be performed in one of two ways, by direct inoculation (direct transfer) or by membrane filtration.

In direct inoculation, the product samples are put aseptically into the microbiological recovery medium and incubated. Clearly this approach is only suited to products that are not likely to be inhibitory to the growth of microorganisms in the recovery medium. An incubation period of 14 days is specified.

In the membrane filtration method, the product samples are put aseptically into a volume of noninhibitory diluent and then passed through a sterile 0.45- μm membrane filter (Fig. 1). The membrane is rinsed through with additional volumes of diluent, then aseptically cut in half. Half is

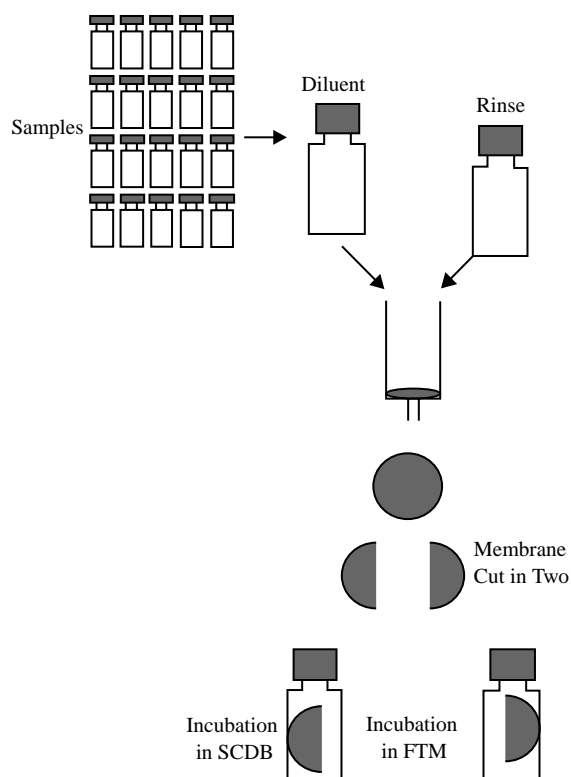

Fig. 1 Generalized scheme for the Test for Sterility by the membrane filtration method.

transferred to a container of soybean casein digest medium (SCDM) and the other to fluid thioglycollate medium (FTM).

A variation of membrane filtration is the use of “closed” systems such as the Millipore Steritest[®] system. At the heart of the Steritest system are two presterilized canisters, each with a membrane filter sealed into its base. The product under test is inoculated into its diluent and transferred via a peristaltic pump into the canisters and through the two membranes. During transfer the diluent is automatically split in two parts. After product filtration, the media are transferred into the canisters, SCDM to one canister and FTM to the other, by the same means. No manipulation of the membranes is required. The canisters are incubated at the temperatures specified in the pharmacopoeias.

Whichever variant of the membrane filtration method is used, SCDM is incubated at 20–25°C and the FTM at 30–35°C for 14 days.

Before 1999, the pharmacopoeias allowed incubation for only 7 days. Now the USP allows 7-day incubation only for terminally sterilized products. This extension of the incubation period from 7 to 14 days is a curious situation. The stimulus was an article published by the

Australian Regulatory Agency (3) indicating that it was possible for some drug products to be contaminated with microorganisms that would require more than 7 days of incubation to produce demonstrable growth under the conditions of the Test for Sterility. This was not, however, a remarkable new discovery. Brewer and Schmitt (4) observed (albeit with ethylene oxide sterilized medical devices) in 1966 that “slow growing” microorganisms (e.g., micrococci and diphtheroids) might take up to 4 weeks to produce demonstrable growth under the conditions of the USP Test for Sterility. There has been no actual evidence of patients having come to harm as a result of requiring only 7 days of incubation in the Test for Sterility. One can only suggest that some compromise was reached during the “harmonization” discussions, and the benefit must be for exporters to Australia where the “preharmonization” Test for Sterility (5) was far more demanding and restrictive.

Conditions for sterility testing

The Test for Sterility is vulnerable to false-positive and false-negative results. A false-positive means that a genuinely sterile product fails the test because of incidental contamination during the preparation of the sample or during the Test. A false-negative means that a nonsterile product passes the Test because viable contaminants fail to grow.

Both circumstances can have serious consequences, but false-positives are less likely to go unnoticed because high frequencies of false-positives have a commercial impact, at least delaying the release of product and at worst leading to suspension of manufacture.

The avoidance of false-negatives is addressed at length in the pharmacopoeias. Each batch of medium used in the Test for Sterility must have been shown to be capable of supporting the growth of low inocula of a specified array of microorganisms. Each Test for Sterility applicable to each specific product must be validated by repeated demonstration that the viabilities of low inocula of a specified array of microorganisms are not inhibited by product traces contained in the medium (direct inoculation) or on the membrane filter.

The pharmacopoeial attitude to false-positives changed in 1999, beginning in the 8th Supplement to USP 23 and in the 1999 Supplement of PhEur. An expectation of some level of false-positives had been tolerated in the Test for Sterility since its inception. This was in acknowledgement of there being a finite probability of the Test becoming contaminated as a result of the large number of aseptic manipulations required in its performance. However, times and technologies have changed.

When the Test for Sterility was first published in the 1930s, it was, at best, being done in glove boxes. The pharmacopoeias recognized the probability of incidental contamination and permitted, in the event of Test failure, an automatic right to retest without further ado. However, with the advent of HEPA filtration and laminar flow technology in the 1960s, the actual frequency of false-positive diminished, but the automatic right to retest remained. Isolation technology became available for doing the Test for Sterility in the last decade of the 20th century.

The automatic right to retest still remained in the pharmacopoeias until in the 1999 revisions, it was recognized that the testing technology was available whereby the probability of incidentally contaminating a Test for Sterility could be less than the probability of the sample actually being nonsterile. The current pharmacopoeial situation is therefore that retesting is only permitted when it can be unequivocally demonstrated that the contaminant in the Test arose incidentally during testing. Strictly, this is not a retest but a repeat Test because the first Test is at fault.

The consequence of this approach is that repeat testing is allowed only with a great deal of information about the microbiological conditions pertaining during the Test, and a large element of professional judgment by the functions held responsible for product release. Many companies have balanced the potential for the increased risk of commercial loss as a result of failures in the Test for Sterility with the potential for regulatory action in the event of disagreement over the judgment involved in repeat testing. They concluded that isolation technology is the only sensible future for the Test for Sterility.

Sterility assurance

Despite the attention, capital and resources given to the Test for Sterility, batches of product cannot be confirmed to be sterile by end-product testing. The Test for Sterility is in fact only a test for a specific broad range of microbial contaminants, and its sampling statistics are not capable of disclosing frequencies of contaminated units that would put patients at risk owing to nonsterility. This has been recognized by the pharmacopoeias, notably the PhEur, which for some years has carried a statement in Section 2.6.1 (formerly V.2.1.1):

... a satisfactory result only indicates that no contaminating microorganism has been found in the sample examined in the conditions of the test. ... The sterility test is ... the only analytical method available to the authorities who have to examine any product for sterility.

Then, how can sterility of batches of supposedly sterile products be confirmed by those functions within companies that are held responsible for product release? The answer is in the use of validated manufacturing processes based on sound scientific evidence that each product unit is most probably sterile.

This raises a second question of how much confidence must one have to claim sterility? The answer to this question, for terminally sterilized products, is that there must be no more than one chance in a million that viable contaminants survive in any one unit. This is called a sterility assurance level (SAL) of 10^{-6} . The answer for aseptically filled products is that the SAL must be as close to 10^{-6} as is technically possible, with the proviso that the degree of protection given to the process must afford no more than one chance in a thousand of any one unit becoming contaminated. This is called a contamination rate of 10^{-3} , and unlike the SAL it relates only to the protection given to the process and not to the potential for contaminants surviving or proliferating in actual products (6, 7).

The concept of the SAL is founded in academic studies of how microbial populations reduce in numbers in response to inimical treatments. In 1945 McCulloch (8) showed that for steam sterilization, a population of bacteria:

exposed to a lethal degree of heat ... decreases in a fairly orderly manner. Thus if 90% of the viable population is killed during the first minute of exposure, approximately 90% of the survivors will

Fig. 2 Exponential inactivation of microorganisms (the survival curve).

be killed during each subsequent minute, which will continue until nearly all of the population is extinct.

This exponential order of inactivation of microbial populations (Fig. 2, the exponential survival curve) has subsequently been demonstrated to be a general characteristic of microorganisms in all processes of sterilization. The logarithmic axis of the exponential survival curve has no zero point. Thus, there can be no time of exposure at any temperature, no dose of radiation no matter how high, that can guarantee 100% inactivation of any microbial population.

Exponential inactivation is the basis of the concept of sterility assurance. If the behavior of microbial populations in response to a particular sterilizing procedure is regular and exponential over the region of the survival curve within which their response can be monitored, then the treatments required to achieve SALs of 10^{-6} can be extrapolated.

The aseptic filling process is not suited to the calculation of SALs in this way. This is because aseptic filling is not based on exponential inactivation and therefore provides no basis for extrapolation. The principle of aseptic manufacture is that, first of all, the drug product and its product-contact packaging components are sterilized to comply with SALs of 10^{-6} , and then they are brought together in ways that are intended to avoid further contamination (asepsis). Ideally, the finished product would still have an SAL of 10^{-6} . The short-fall from this ideal is primarily a function of the technology used in the aseptic filling process. Where sterile isolation technology is being used—this is a developing rather than an established technology at the time of writing in 2000—it is likely that there is very little shortfall. With standard technology, a level of process protection from microorganisms demonstrable through media fills offering a contamination rate of no more than 10^{-3} is nominally acceptable to regulatory bodies worldwide.

Microbiological GMP in the Manufacture of Sterile Drug Products

As far as manufacture is concerned, there are two broad categories of sterile products: those that are terminally sterilized (filled and hermetically sealed within their final containers before being exposed to a sterilization treatment), and those that are aseptically manufactured (the drug product and its product-contact packaging components are sterilized and then brought together in ways that are intended to avoid further contamination. Serious measures to protect the manufacture from microbiological contamination are necessary for both

categories but are clearly most critical in the poststerilization stages of aseptic manufacture.

There are several sources of standards and limits that may be applied to the manufacture of sterile products. They can be divided into sector-specific standards which are focused specifically on the manufacture of sterile pharmaceuticals and generic standards that are focused on particular technologies, irrespective of how the technologies are to be applied.

Sector-specific standards applying to manufacture of sterile drug products

There are five significant sources of sector-specific standards applying to the manufacture of sterile products. Two are mandatory, three are voluntary.

The two mandatory standards are Annex 1 of the European Union's GMPs (9) and the FDA's 1987 *Guideline on Sterile Drug Products Produced by Aseptic Processing* (10). The FDA document is under review at the time of writing this article.

The first of the two nonmandatory standards is contained in Section 1116 of the USP. It should be explained that this is a general chapter of the USP and is not therefore mandatory unless referenced in a USP monograph. At time of writing, Section 1116 is not referenced in any monographs.

The second of the voluntary standards is IS 13408 (11), applying to both medical devices and to pharmaceuticals according to the International Standards Organization (ISO) definition of "healthcare products." Here, it should be explained that the ISO is a voluntary body whose membership is drawn from national standards organizations. ISO standards have no legal authority in any country or territory unless the national standards body elects to adopt the ISO standard instead of publishing its own standards.

The third voluntary standard is The International Society of Pharmaceutical Engineer's (ISPE) *Baseline Pharmaceutical Engineering Guide* (12). This is one of a series of ISPE guidance documents that has limited endorsement by the FDA. It should be understood that only minimal standards are being endorsed and there are many reasons why specific sterile products and applications could be seen by the FDA to require compliance with higher standards.

Working with these five documents is not easy; they use different terminology and definitions and have different emphases that in part, may be a function of the 10-year span that encompasses publication dates. All of them are concerned with controlling microbiological contamination that may arise from the environment, from personnel, and from materials and equipment. Some individual standards within these documents may relate to microbial numbers,

others to physical characteristics that relate to contamination control.

All of these documents stress a requirement for room classifications according to the concentration of nonviable airborne particles at 0.5 μm and larger. The EU GMPs (9) subordinate classification of the various areas applicable to sterile manufacture according a broader based grading system. Grades A to D are defined in terms of a range of independent characteristics such as the concentration of nonviable airborne particles at two sizes in operational and nonoperational conditions, the concentration of airborne viable particles in operational conditions, and several other indices of microbial contamination on surfaces and hands, etc. The inclusion of microbiological limits within this grading system is important in that it emphasizes that it is not solely the concentration of nonviable airborne particles in clean-rooms (room classification) that determines their suitability for manufacture of sterile products.

Generic standards for technologies used in the manufacture of sterile drug products

The most important generic standards applying to technologies used in the manufacture of sterile drug products relate to the protection of manufacture from contamination from the air. The air supply to facilities for sterile manufacture must be filtered, in some specific applications, it must be unidirectional, its velocity may have to be controlled within specified limits, and there must be pressure differentials between adjacent areas.

In the late 1990s, there had been a great deal of ISO activity in the harmonization of various standards applying to air quality (13). The first three parts address classification of air cleanliness, methods for testing and monitoring, and metrology. Parts 1 and 2 cover much of the ground but are not identical to FS 209 (14) (see below). The significant question emerging as these standards are published has to do with the reaction of the pharmaceutical regulatory agencies. Whereas we can with confidence be sure that the standards applying to the specifications of HEPA filter media and to the in situ HEPA filter integrity test will be accepted, there still are some doubts about the standard for room classification.

Both of the two mandatory sector-specific standards (9, 10) currently require room classification according to Federal Standard 209. This is a U.S. government standard; its current revision is FS 209E (14), and it will not be automatically replaced by IS 14644 (13). Thus, we are dependent on the next revision of Annex 1 of the EU GMPs (9) and of the FDA's *Guideline on Sterile Drug Products Produced by Aseptic Processing* (10) to

determine whether they will be adopted for the manufacture of sterile drug products.

Validation and Control of Sterilization Processes

Although there are many sterilization processes used in association with the manufacture of sterile drug products, the three primary processes are steam sterilization, dry heat sterilization, and sterile filtration. Dry heat sterilization is, in the context of the manufacture of sterile parenteral products, a subset of dry heat depyrogenation (see below).

Steam sterilization

Steam sterilization is widely used as a terminal process for drug products in glass ampules, vials, syringes, and plastic containers. It is also used for sterilizing closures, filters, manufacturing equipment, and cleaning equipment, etc.

Steam sterilization in autoclaves has a long and strong scientific basis (see above). The essence of validation of steam sterilization processes is to demonstrate that temperature and time conditions are being achieved uniformly through every item included the autoclave load and that the lethality being achieved in practical situations corresponds to that which would be expected from sterilization theory.

Thus, compliance with limits for temperature uniformity throughout empty autoclaves (heat distribution studies) is an index of the way in which the autoclaves are engineered. Compliance with limits for temperature uniformity within items loaded into the autoclaves (heat penetration) is an index of the way in which items are wrapped for sterilization (where applicable) and how they are loaded into the autoclaves in relation to the positions of steam inlets, drains, racks, trays, and thermal sensors.

With modern autoclaves, the major impediment of concern to successful sterilization is air in porous loads. Air may be present as a contaminant of the steam supply such that the temperatures theoretically achievable at particular steam pressures are depressed, or air may be present within the load, insulating it from the contact with the steam required for predictable lethality.

Pure steam generators are designed to deliver steam of satisfactory quality—standards are published in a UK document, Health Technical Memorandum (HTM) 2010 (15)—but noncondensable gas like air and nitrogen can accumulate in the steam through poorly insulated and trapped distribution systems and therefore should be tested periodically close to point of use. Autoclaves suited to sterilization of porous loads require some form of air removal, most often by deep pulsed vacuums, before the introduction of steam. The effectiveness of air removal is

difficult to monitor by physical means; air entrapment may be a local phenomenon in particular locations in loads, in particular materials (e.g., in cartridge filters), or where items come into contact with one another (e.g., with rubber closures in bulk). Therefore, it is normal to use biological indicators to ensure that there is correspondence between theoretical and practical reality. Biovalidation of steam sterilization, although done extensively, is all very complex and, to an extent, a poorly understood. The basics are that a suitable biological indicator should be resistant to sterilization by steam (but not necessarily the most resistant microorganism known—spores of *Bacillus stearothermophilus*) are approved by the USP, PhEur, and others and are most often used. The biovalidation cycle must be of lower thermal lethality than the lowest thermal lethality allowable within the routine production-cycle specification. Some interesting reviews of biovalidation of steam sterilization have been published by Halls (16) and by Agalloco and colleagues (17).

Steam sterilization is not confined to autoclaves. Many items of manufacturing equipment, including some quite massive applications to vessels, pipe-work, filters, etc., are now sterilized in place with steam (SIP). It is essential that the equipment holds pressure, that air is removed, and that condensation does not accumulate in low points of the system. Biological validation is generally unsophisticated and is normally done by ensuring that the process inactivates several biological challenge test pieces, each carrying 10^6 spores of *Bacillus stearothermophilus* (D_{121} -values undefined but presumably meeting the pharmacopoeial criteria of equal to or greater than 1.5 min) placed at critical points. Academically, it is problematic to equate this approach with the sterility assurance level concept that applies to the sterilization of groups of items.

Steam sterilization processes are monitored for compliance with strict specifications of temperature, pressure, and time. Routine monitoring with biological indicators is not necessary. Indeed, any item of steam sterilizing equipment that is operating so erratically as to merit routine monitoring with biological indicators should be replaced.

Sterilization by filtration

Filtration is a means of sterilizing fluids by removing, rather than inactivating, microorganisms. The sterilization of liquids is used extensively in aseptic manufacture, sterilization of gases is used both in terminal sterilization and in aseptic manufacture. Most applications use cellulose esters, polyvinylidene fluoride, polytetrafluoroethylene, nylon, and other polymeric materials. The removal of microorganisms from fluids by passage through filters is very complex; sieving, or surface retention, is only one of a

series of mechanisms that depend on interactions among the chemistry and surface characteristics of the membrane, the microorganisms, and the suspending fluid (18).

The FDA (10) defines sterilizing filters as those that have pore-size ratings of 0.22 μm or smaller and relates this to a microbiological particle passage test using *Pseudomonas (Brevundimonas) diminuta*:

A sterilizing filter is one which, when challenged with the microorganism *Pseudomonas diminuta*, at a minimum concentration of 10^7 organisms per cm^2 of filter surface will produce a sterile effluent.

It is essential that the microbiological particle passage test is performed as part of the development of new sterile formulations. Because of its very specialized nature, the test is normally performed only by the filter manufacturers, who then provide limits for secondary physical tests (e.g., bubble point, pressure decay, forward flow, etc.), which can be applied to verify the pore size rating and integrity of the membrane filters.

Maintenance of Sterility after Product Release

The sterility of a sterile dosage form can only be guaranteed while it is protected from the surrounding nonsterile environment within a container made from materials impermeable to microbial penetration.

Container and closure systems for sterile products must be capable of withstanding process conditions, storage, and transport without compromising the sterility of the product. This has been recently emphasized by the FDA, which has omitted a former obligation to provide data from the Test for Sterility in stability program for new sterile products in favor of verifying the microbial integrity of the container-closure system (19).

There are no standard methods for verifying microbiological integrity of container-closure systems. Documents such as that published by the Parenteral Society in 1992 (20) and the PDA in 1998 (21) may be helpful in relating microbiological integrity to secondary physical tests, but they do not specify detailed microbiological test methods.

There are two general approaches, wet tests and aerosol challenge tests. Wet tests consider penetration of microorganisms in liquid suspension into sealed containers usually previously filled with sterile medium. The basic assumption is that the most vulnerable route for penetration of liquid filled containers by microorganisms is in the event of a continuous liquid film or “bridge” forming between the outside and the inside of a container. Aerosol challenge tests are less critical than wet tests and

should be applied only when total exclusion of moisture from the containment system can be ensured by secondary barriers.

No discussion of maintenance of sterility is complete without addressing multiple-dose ophthalmic presentations. The normal circumstances for sterile parenteral products are that they are unit dose or, if multiple dose, they are penetrated only by sterile transfer devices (syringes, giving sets, etc.) and used on one patient only. This is not the case for ophthalmic ointments and drops: unit-dose presentations are quite unusual and generally used only in hospital practice, for example, after eye surgery.

The multiple-dose presentation is the norm for ophthalmic products. The container is breached at first use and therefore has no further microbiological integrity over subsequent applications by the patient for an undefined period possibly up to the expiration date of the product. Under these circumstances, contamination of the drug products can and must occur; the proliferation of the contaminating microorganisms the products is controlled by use of antimicrobial and preserved formulations. After opening they are, effectively, non-sterile products. Why, therefore, do we go to the trouble to manufacture ophthalmic ointments and drops as sterile products? There is no clear answer to this question; it is an anomaly. It has been a worldwide regulatory requirement "since the beginning of time" for ophthalmic products to be manufactured as sterile, and there is undoubtedly little point in contesting its logic or consistency. Another possible anomaly concerning sterility may be arising from the FDA's 1997 proposal (25) to require all aqueous inhalation products to be sterile. This example is anomalous because only in very exceptional circumstances is the equipment used to administer inhalation products supplied and maintained sterile and, of course, neither are the nasopharyngeal and bronchial passages of the patient.

Pyrogens, Lipopolysaccharides, and Bacterial Endotoxins

Parenteral products are expected to be sterile because of the risk of infection. Another critical biological characteristic is that they should be free from pyrogens. Pyrogens are substances that, when injected in sufficient amounts into the human body, give rise to a variety of extremely unpleasant symptoms of which the most recognizable is a rise in body temperature. In extreme conditions, the rise in body temperature can be so rapid and to such an extent that the patient dies (endotoxic shock). In the pharmacopeias, pyrogenic products have

traditionally been defined in terms of the temperature rise induced in injected rabbits.

The causative agent of the pyrogenic response is lipopolysaccharide. This material is of microbiological origin, and although all bacteria appear to be capable of producing lipopolysaccharide, it is found primarily in the cell envelope of Gram-negative species. Naturally occurring lipopolysaccharide is referred to as bacterial endotoxin.

Bacterial endotoxin reacts with a high degree of specificity with a "clottable protein" contained in the amoebocyte cells of the horseshoe crab (*Limulus polyphemus*). This has allowed the development of in vitro testing of drug products and other substances for bacterial endotoxins. The pharmacopeias are progressively replacing their former requirements for in vivo rabbit pyrogen testing of parenteral products with the in vitro *Limulus* Amoebocyte Lysate (LAL) test. There are a variety of test systems now marketed (gel clot, turbidometric, chromogenic, etc.), but the pharmacopeias regard the gel clot method as the reference test. In the gel clot method for the LAL test, a quantity of LAL reagent of defined sensitivity (λ), e.g., 0.03 EU (endotoxin units) per milliliter, is mixed with an equal quantity of the product under test (or a dilution thereof). The mixture is incubated for a defined period and then inverted. The production of a gel is evidence of bacterial endotoxin in the product sample at a concentration equal to or greater than the sensitivity of the LAL reagent.

Product endotoxin limits are based on dosage regimes (22) derived from a formula K/M , where K is the threshold dose for any substance capable of giving a pyrogenic response in humans. With some exceptions K has been given a fixed value of 5 EU/kg body weight of the patient, and adult patient body weight is standardized to 70 kg for calculation. M is the maximum dose of endotoxin per kilogram of body weight of a patient that is permitted to be given in a single 1-hr period.

Endotoxin limits are therefore unique to each dosage form. Because K is fixed, it is usually only necessary to determine M from the maximum human dosage indicated in the product instructions.

The validation and performance of the endotoxin test require rather elaborate and detailed attention to use of controls. These details are specified in Section 85 of the USP harmonized with Section 2.6.14 of the PhEur.

Control of bacterial endotoxins

Although bacterial endotoxins are of microbiological origin, they are not lost with loss of viability. Of the sterilization processes commonly used in the manufacture

of sterile parenteral dosage forms (see above), only dry heat is capable of destroying bacterial endotoxins in a reasonable time frame (23). There is therefore no practical way of removing bacterial endotoxins from finished drug products; thus, they must be controlled at source.

The most likely source of bacterial endotoxins is water and product-contact packaging components that have been in contact with water. This is because bacterial endotoxins are most frequently found associated with Gram-negative bacteria, and Gram-negative bacteria have evolved to be primarily waterborne.

Water used in manufacture of sterile parenteral products must comply with pharmacopoeial limits for endotoxin of no more than 0.25 EU/ml (limits in the USP and PhEur for water for injection). In principle water complying with this limit can be produced by distillation, reverse osmosis, and ultrafiltration. PhEur allows only distillation to be used for the manufacture of ingredient water for parenteral products; the USP allows distillation and reverse osmosis (although reverse osmosis is rarely used in the United States, perhaps because of FDA pressure). Only the Japanese Pharmacopoeia allows water for injection to be manufactured using ultrafiltration.

Product-contact packaging components, such as glass vials, which are required to be sterile, are usually sterilized and depyrogenated by dry heat in ovens or tunnels. The standard required by the FDA for acceptable depyrogenation processes (10) is that they should be capable of reducing a bacterial endotoxin challenge by a factor of 10^{-3} (3 logs). Unfortunately, inactivation of bacterial endotoxins by dry heat is complex, and satisfactory process specifications are difficult to predict; inactivation of purified lipopolysaccharide may approximate to pseudo-second-order reaction kinetics (24). It appears that there may be a threshold temperature of approximately 160–170°C, below which a 3-log reduction of bacterial endotoxin cannot be achieved regardless of time of exposure.

MICROBIAL CONTROL OF NONSTERILE PRODUCTS

Nonsterile dosage forms are a diverse group of products. The microbiological risks that nonsterile products present to the patient are equally diverse. A single microbiological standard cannot sensibly be applied to all nonsterile products, and this is well reflected by pharmacopoeial and regulatory requirements. Similarly, there can be no single standard applied to the microbiological control and

prevention of contamination during the manufacture of nonsterile products.

The Microbial Limit Test

Microbial limit standards for some, but not all, nonsterile dosage forms are given in USP monographs. PhEur takes a slightly different approach. Section 5.1.4 lists microbiological criteria for two categories of nonsterile pharmaceutical products on the basis of usage. One of these categories is for products for topical and respiratory use, the other for products for oral and rectal administration. Guidance to methods suited to testing products for compliance with these standards is given in Section 61 of USP and Section V.2.1.8 of the PhEur.

In setting appropriate limits for particular nonsterile products, both pharmacopoeias take account of the significance of microorganisms to different types of product, to the way in which the product is used, and to the potential hazard to the patient. For instance, 47 of 48 monographs defining microbial limits listed in USP 24 for oral dosage forms restrict microorganisms (*E. coli* and/or *Salmonella*) that are pathogenic by gastrointestinal ingestion. These are, of course, not the only microorganisms that could endanger a patient taking an oral dosage form. They have been selected as indicators of the general type because there are well defined methods for their recovery and they are easily recognizable in culture. Similarly, the USP typically (but not universally) restricts from topical products only those microorganisms (*Staphylococcus aureus*, *Pseudomonas aeruginosa*) that have the potential to cause skin infections. Sixty-seven of 68 monographs in the USP 24 require the absence of at least these two species, and of these 67 only 11 have additional requirements. These limits applying to the absence of specific indicator microorganisms appropriate to the product's usage may be supplemented by general hygiene restrictions on total numbers of microorganisms per gram or milliliter (typically to no more than 100 cfu per gram or milliliter). A very similar overall approach is taken by the PhEur.

Requirements are not specified in the pharmacopoeias for sample sizes appropriate to testing batches of nonsterile products for compliance with microbial limits. The test is destructive to the product, and it is extremely unlikely that statistically valid sampling plans are in use anywhere; samples composed of 10 1-g amounts taken from 10 separate 15-g tubes of cream, or of three 3.3-ml amounts taken from three separate 500-ml bottles of syrup, may be typical.

The Microbial Limit Test is, like the Test for Sterility, only confirmatory. It is not generally mandatory to test

each batch of every nonsterile product for compliance with microbial limits. The exception is in the United States where it is mandatory to test every batch of nonsterile product. At the time of writing (early 2001), the FDA has proposed a relaxation of this rule for future registrations. However, in the case of tablets there is no requirement to register microbial limits, and therefore testing is not mandatory. The logic behind this is that the water content of tablets is too low to allow proliferation of microbiological contaminants.

It should also be kept in mind that the major regulatory agencies (FDA, MCA) would not want to have the pharmacopoeial limits on numbers of microorganisms perceived as tolerance of microorganisms contaminating and proliferating in nonsterile products. The acceptance of these limits is only an acknowledgment of the reality that when products are not manufactured as sterile, some microbiological contamination is inevitable. Well formulated nonsterile products manufactured under microbiologically controlled conditions are extremely unlikely to have bioburdens approaching the pharmacopoeial limits (typically 100 cfu per gram or milliliter). Most regulatory bodies now expect companies to set tighter microbial limits on their nonsterile products based on their typical results, these being seen as alert limits indicative of some loss of microbiological control if exceeded.

Microbiological GMP in the Manufacture of Nonsterile Drug Products

The extent to which the microbiological controls are required to be applied in the manufacture of nonsterile dosage forms is primarily a function of two factors: consequences of infection to the patients and probability of microorganisms proliferating in the product.

The seriousness of the risk to patients of infection from nonsterile dosage forms is primarily dictated by the route of administration of the dosage form. The probability of contaminating microorganisms surviving

and proliferating in a nonsterile dosage form is generally a function of its water content. Bearing these two concepts in mind, it is possible to classify the extent to which microbiological controls are required in the manufacture of nonsterile dosage forms according to a "good hotel guide" approach such as that given in Table 1. The precise allocation of "stars" is a matter of opinion, but at one extreme there is little doubt that aqueous inhalations merit "5-star" microbiological controls in manufacture, and possibly may soon be required to be sterile (25). Near the other extreme, the FDA, for example, does not require microbial limits to be registered for solid oral dosage forms.

There is little published guidance to microbiological controls for nonsterile manufacture. Equipment and facilities should be designed to minimize the opportunities for contact with air, personnel, and water.

Exposure to air is unavoidable, either as local atmospheric (environmental) air or as air from compressors used to operate manufacturing equipment and in fluid bed dryers, etc. Even for "1-star" nonsterile manufacture, the air supplied to areas used for manufacture and filling should be filtered. HEPA filters should be used in "5-star" nonsterile manufacture but are generally not necessary in "1-star," intermediate classifications of manufacture, requiring decisions on air filtration to be made from sensible risk assessments.

Personnel should be restricted from all areas of pharmaceutical manufacture to those who are necessary. Protection from contamination from personnel is by training in hygiene, enforcement of hygiene rules, and provision of protective clothing. Hair is the major source of contamination from personnel, and "street clothes" is the second most significant source. Hair-covers should be provided and worn properly in all areas of sterile manufacture; beards, moustaches, and other excessive facial hair should be covered. Overall sleeves should extend to the wrist and be elasticated or studded to provide a neat fit. Because dogs are still allowed to soil the streets,

Table 1 Classification of nonsterile manufacture according to the need for microbiological controls

Route of administration	Type of nonsterile dosage form		
	Aqueous liquids	Nonaqueous fluids	Solid dosage forms
Inhalation	☆☆☆☆☆	☆☆☆☆	☆☆☆☆☆
Intranasal, intrabuccal	☆☆☆☆	☆☆☆	☆☆☆
Topical	☆☆☆☆	☆☆	☆☆
Oral	☆☆☆	☆	☆
Anal	☆☆	☆	☆

protective footwear or shoe covers should be provided to all personnel allowed to enter pharmaceutical manufacturing areas.

Water is often the major ingredient in nonsterile products. When it is used as an ingredient, it must meet the pharmacopoeial limit for purified water of not more than 100 cfu/ml. Well designed and operated pharmaceutical purified water production and distribution set ups meet far tighter standards than these. Water is also often the principal cleaning fluid for equipment and facilities and is therefore unavoidable. It is a potent source of contamination because it usually contains sufficient nutrients to allow survival of metabolically versatile microorganisms, particularly *Pseudomonas spp.*

When water is left to stand, *Pseudomonas spp.* do not only survive, but increase in number. Water should not be permitted to stand on equipment (particularly in crannies and crevices), on floors, or in sinks and wash bays. Contamination spreads with water that forms films over surfaces and on the hands and clothing of personnel. Waterborne contaminants may be aerosolized by vibrations or when water falls more than a few centimeters.

To restrict the opportunity for contamination from water, there should be air breaks of approximately 5 cm installed between equipment drains and the tun dishes leading to foul drains.

The FDA has published guidances on the design and control of water systems (26).

Maintenance of Microbiological Quality of Nonsterile Products after Release

It is not desirable for those few microorganisms that may be present in nonsterile products at the time of release to increase to numbers to levels at which they may present a risk of infection to the patient or "spoil" the product.

Additional contamination in the period up to the first use by the patient or healthcare professional is provided by the packaging. It is neither necessary nor usual to find that nonsterile product packaging has been specifically designed or tested to be impermeable to microbiological contamination. On the other hand, many products are given good microbiological protection as a secondary consequence of the protection given to the stability of their active ingredients, etc. For instance, tablets packed individually in strips or foils are microbiologically protected until time of use. It is also unlikely for microorganisms to be able to contaminate pressurized metered-dose inhaler containers.

Microbiological protection of multiple-dose presentations such as liquid inhalations, nasal sprays, oral liquids, creams, and lotions is more complex. Once opened they are susceptible to microbiological contamination. If they are aqueous-based, they are in principle susceptible to proliferation of these "new" contaminants. To avoid this, they are formulated with antimicrobial agents or preservatives and are expected to be able to comply with preservative efficacy standards specified in the pharmacopoeias. Preservative efficacy tests (not harmonized) are described in Section 51 of the USP and Section VIII.14 of the PhEur (Fig. 3).

METERED DOSE INHALERS

Sandy J.M. Munro

Alan L. Cripps

GlaxoSmithKline, Ware, Hertfordshire, United Kingdom

INTRODUCTION

Metered dose inhalers (MDIs) are pharmaceutical delivery systems designed for oral or nasal use, which deliver discrete doses of aerosolized medicament to the respiratory tract. The MDI contains the active substance, dissolved or suspended in a liquefied propellant system held in a pressurized container that is sealed with a metering valve. Actuation of the valve discharges a metered dose of medicament as an aerosol spray through an actuator during oral or nasal inhalation.

The MDI may provide up to several hundred actuations, each containing typically from about 10 to 500 μg of drug dispersed in a 25 to 100 μl metered volume of liquid. The discharged liquid undergoes flash evaporation of the propellant to produce a finely dispersed aerosol spray. The deposition, and hence the clinical efficacy, are critically dependent on the mass of inhaled particles, which must have an appropriate aerodynamic size, typically less than 5 μm , to be deposited in the lungs (the respirable fraction) (1).

The first MDI products were developed by Riker Laboratories and marketed in 1956, using a newly patented design of metering valve. In most countries the MDI is now established as the principal dosage form of inhalation drug therapy for bronchial asthma and chronic obstructive pulmonary disease (COPD). Since its introduction, MDI technology has evolved steadily. However, with the phase-out in the commercial use of chlorofluorocarbon (CFC) propellants, which have been the mainstay of pharmaceutical MDIs, the pace of MDI technology development has accelerated with the transition to hydrofluorocarbon (HFC) propellants (2).

Despite their apparent simplicity in use, MDIs are complex devices involving the integration of formulation, container, metering valve and actuator (Fig. 1). Changes to any one of these components will affect the overall performance of the MDI, which is designed to ensure that the delivered dose and the particle size distribution of the drug in the aerosol spray are consistent over both the labelled number of actuations in the MDI and for the duration of the shelf-life (3).

The design and evaluation of MDIs are reviewed in references (4–7).

PROPELLANTS

The propellant or propellant mixture used in the MDI provides the energy necessary to generate a fine aerosol of drug particles suitable for delivery to the lungs or nasal cavity. Liquefied compressed gases are preferred over nonliquefied compressed gases such as nitrogen or carbon dioxide because they offer the following critical advantages for inhalation therapy:

- The discharge of defined aliquots of propellant from the MDI will undergo flash evaporation to give an aerosol of very small particles.
- The pressure inside the MDI remains consistent throughout the use of the entire contents, thus ensuring that the aerosol characteristics remain uniform during repeated discharges. At constant temperature, the vapor pressure remains constant while liquefied propellant remains. In contrast, aerosols generated using nonliquefied compressed gas coarsen during emptying of the MDI due to the decrease in gas pressure.

However, unlike nonliquefied compressed gases, the vapor pressure of liquefied propellants decreases significantly with decreases in temperature, such that below a certain temperature, the flash evaporation process is sufficiently retarded to give poor aerosol formation. For the propellants commonly used in MDIs, unacceptable aerosol formation is likely to occur below 0°C.

The ideal propellant for use in an MDI will exhibit the following properties (8):

- Nontoxic
- Inert and unreactive in the formulation
- Chemically stable under a range of conditions
- High purity
- Acceptable taste and odor
- Compatible with the packaging components (can, valve, actuator)

- Suitable vapor pressure
- Suitable density to facilitate suspension stability
- Suitable solvency properties
- Preferably nonflammable
- Acceptable cost

Until recently, only three chlorofluorocarbon (CFC) propellants, namely CFCs 11, 12 and 114 (Table 1), had been approved worldwide for use in medical MDIs. Their widespread acceptance was due to their ability to substantially meet the ideal propellant properties. All the CFC MDIs that are currently marketed employ CFC 12 as the major constituent mixed with either CFC 11 or with a mixture of CFC 11 and CFC 114. These mixtures of propellants closely obey Raoult's law and therefore the blend selected can be used to give a defined vapor pressure (Table 1). The inclusion of CFC 11 in the formulation also offered advantages in that it increased the solvency of most propellant systems, thereby facilitating the dissolution of surfactants in suspension formulations. By virtue of it being a liquid below 24°C, it was used as the primary dispersion medium for either suspending or dissolving the drug.

In 1974, Rowland and Molina (9) published their hypothesis that CFCs could lead to the depletion of stratospheric ozone. With confirmation of this theory through subsequent studies, an international agreement, The Montreal Protocol on Substances that Deplete the Ozone Layer (10), was drawn up and set in motion a timetable for the phase-out of both the manufacture and use of CFCs. Although the consumption of CFCs in inhalation products is probably insignificant in ozone depletion, representing approximately 0.4% of the worldwide CFC consumption in 1986 (11), the pharmaceutical industry has been working since 1987 to find alternative propellants with which to replace the CFCs used in MDIs. The establishment of the safety and suitability of such alternatives for use in medical aerosols is a lengthy and

complex process. As a consequence, MDIs have been identified as an essential use of CFCs and have remained exempt from the provisions of the Montreal Protocol during the transition process.

The search for propellants of low or zero ozone depletion potential (ODP) has led to the identification of a number of potential compounds. A number of chemical industry consortia were established to investigate the acute toxicity of the most promising candidates under The Programme for Alternative Fluorocarbon Toxicity Testing (PAFTT) (8).

The use of HCFCs has been considered, although they still have an appreciable ODP. For instance, HCFC 22 could provide a technically satisfactory replacement for CFC 12. However, revisions to the Montreal Protocol in 1990 require the phase-out of HCFCs by 2020.

The use of hydrocarbons such as isobutane is common in general consumer aerosols. However, their odor and flammability have deterred their use in medical aerosols although purer grades, which are odorless are now available. Dimethylether (DME) is used similarly because it combines zero ODP with superior solvency for various active components and appreciable miscibility with water, which may be important in the formulation. However, the high flammability of both the hydrocarbons and DME would require expensive modification of facilities for the manufacture, storage, and transportation of MDIs. Flame extension studies have shown that the flammability of these propellants is unlikely to present a significant risk during inhalation use due to the small metered volumes (12). Another challenge in the use of both hydrocarbons and DME as propellants in suspension MDI formulations may be their low density, compared with most drug substances, which would give rise to poor suspension stability leading to the potential for inconsistent dose delivery.

Of the alternatives identified, the hydrofluoroalkanes (HFAs) or HFCs were targeted for development as replacements for the CFCs in MDIs. Within this class, 134a and 227ea were adopted for inhalation toxicity testing by two consortia of pharmaceutical companies: IPACT 1 for 134a and IPACT 2 for 227ea (IPACT: International Pharmaceutical Aerosol Consortium for Toxicity Testing). These programs established the safety profile of both propellants, which has led to the recommendation by the Committee of Proprietary Medicinal Products (CPMP) of their suitability for use in MDIs (13).

The vapor pressure of 134a is higher than that of 227ea, but both are seen as alternatives for CFC 12. To date, no suitable replacement for CFC 11 has been identified. In some HFA MDI formulations, ethanol has been used as a

Fig. 1 Sectional view of a metered dose inhaler.

cosolvent to enhance the solubility of surfactants in place of CFC 11. The HFA propellants meet many of the criteria of the ideal propellant for use in an MDI, although the solvency properties of both 134a and 227ea are markedly different from those of the CFCs. Hence the conventional surfactants used in CFC MDIs were found to be incompatible. As a consequence, the development of HFA MDIs has required the resolution of a significant number of technical problems (3).

FORMULATION

In general, MDI formulations can take the form of either suspensions or solutions. Traditionally the preferred route has been to formulate a suspension of the micronized drug substance in the liquid propellant (CFC or HFA). In some cases, additional excipients (e.g., surfactants and/or cosolvents) have been added to improve the quality of the dispersion. The various MDI formulation options are described in detail later together with a description of some of the alternative options for the input drug substance.

Historical Overview of CFC-Based MDI Formulations

These typically comprised a suspension of the micronized drug substance in various ratios of propellants 12 and 11 and/or 114. A surfactant was usually added to improve the suspension behavior by decreasing the rate of flocculation and sedimentation or creaming and also by reducing the amount of drug deposition on the internal surfaces of the valve and container (4). The addition of a surfactant to moderate the suspension behavior and reduce internal drug deposition, can make the valve sampling and hence the dose delivery more reliable. Some CFC MDI products have also been formulated as solutions (14). Typically, the drug substance is solubilized by adding a small quantity of ethanol. The potential strengths and weaknesses of both suspension and solution formulations are discussed in detail in the following section, which covers formulation options for HFA-based MDIs (15).

HFA MDI Formulations

Input drug substance

The microfine drug powder used in suspension-based MDIs has typically been prepared using an air-driven fluid energy mill and this is still the method predominantly used for the currently marketed suspension-based MDIs.

In recent years, there has been a recognition that although the micronization process is a cost-effective method of producing a material with the correct particle size distribution for inhalation, the process, which relies on particle–particle collisions and attrition to gradually reduce the particle size, may also impart some undesirable characteristics to the particles produced.

As a consequence of the limitations of the micronization process, various particle engineering (16, 17) techniques are under investigation with a view to providing superior input microfine drug for MDI manufacture. Some of these techniques, for example, SEDS (Solution Enhanced Dispersion by Supercritical Fluids) (18) rely on alternative crystallization technologies to go straight from a solution of the required drug substance to crystals with exactly the required surface characteristics and particle size distribution without going through the high-energy micronization process. Other techniques extend spray drying technologies to produce particles with controlled density, porosity, particle size distribution, and shape as well as allow for coformulation with other solid excipients to produce particles with controlled drug release characteristics as well as potentially controlled regional deposition within the lung (19, 20). Particle engineering techniques may also offer enhanced performance to meet increasingly stringent regulatory requirements (21, 22).

HFA MDI solution formulations

In an HFA MDI solution formulation, the drug is completely dissolved using an HFA propellant (e.g., 134a) plus an appropriate cosolvent to produce a pure solution product. The cosolvent most commonly used is ethanol. This approach has been used successfully to produce a solution aerosol product for BDP (23). There are a number of advantages to a formulation of this type:

1. Potentially fewer issues around homogeneous valve sampling from the bulk.
2. As in the case of the BDP solution aerosol, enhanced efficiency of aerosolization, leading to high lung deposition compared with an equivalent suspension product.
3. Overcomes issues with suspension systems where the drug has measurable solubility in the propellant, i.e., formulation does not suffer from particle growth issues.
4. Provided there is always sufficient cosolvent present to preserve the true solution status of the product, no issues with drug deposition on the valve components and container.
5. May be a simpler filling process than for a suspension-based HF MDI.

There are also a number of disadvantages to true solution MDI products:

1. Solution products can be more susceptible to drug losses into the elastomeric components of the valve than for an equivalent suspension product. Drug losses of this kind can be an issue particularly for low dose products.
2. There are currently few options beyond ethanol in terms of cosolvents that would be Generally Regarded As Safe (GRAS). Thus, to develop a solution formulation using a cosolvent other than ethanol could necessitate an extensive toxicology testing program. Of the currently available respiratory drugs, there are few that are sufficiently soluble in ethanol or sufficiently low in strength to easily yield a solution product.
3. If too much ethanol is used to dissolve the drug, the vapor pressure may drop below that required to achieve efficient atomization.
4. If the product under development is transitioning from an existing CFC suspension-based product, it may be difficult to replicate the fine particle mass, the particle size distribution and/or the absorption characteristics. This can lead to problems in providing a seamless transition from the CFC product because of the potential to have to change the dose and because the product can smell and feel different to the original suspension formulation.

More recently, other (less volatile) organic modifiers, e.g., glycerol, have been added to solution-based HFA MDIs to modify the particle size distribution so that it more closely resembles that of the originator suspension product (24).

HFA MDI suspension formulations

There are a number of possible approaches to a suspension-based formulation. A micronized drug can simply be suspended in an HFA propellant or a mixture of HFA propellants. The principal advantage to a formulation of this type is that it is simple and contains no additional excipients with their inherent toxicological implications. The performance of a formulation of this simplicity will be dependent on the inherent properties of the drug substance and the propellants used. For example, if the drug substance is significantly more dense than the propellant(s) is, then rapid sedimentation of the suspension is likely to occur following agitation. This could create issues in terms of the valve sampling homogeneously from the bulk container contents. Further differences between the drug and propellant in terms of relative hydrophobicities and hydrophilicities can also result in rapid flocculation immediately postshaking or a tendency for the drug to

deposit on the MDI container walls and valve components. For the approach of creating a dispersion of drug in propellant to be successful, the drug should essentially be insoluble in the propellant(s) to provide good product stability. The formulation should also possess reasonable characteristics such that the suspension is easy to redisperse so that the valve still samples homogeneously from the bulk suspension contents in a time-scale consistent with the gaps a patient would typically leave between shaking and firing the inhaler. The tendency for drug to deposit on the inner surfaces of the container and valve can be controlled via sophisticated packaging technologies, e.g., can coating, making this kind of MDI formulation successful for a number of drug substances.

For CFC-based suspension formulations, a surfactant was typically included. A variety of surfactants were used in these systems, e.g., lecithin, oleic acid, sorbitan trioleate (14). All these surfactants were freely soluble in the CFC propellants and allowed for a degree of control over the suspension characteristics. Rates of flocculation, sedimentation, and creaming could be controlled and deposition on the internal container components was minimized. The transition to HFA-based MDIs has created significant issues in that none of the surfactants, previously used with the CFC products are soluble in HFA propellants alone. Some formulations have still used these surfactants, but the addition of a cosolvent (ethanol) has been required to solubilize the surfactant.

In addition to HFA formulations using the traditional surfactants plus cosolvents, there has also been some research work to identify novel surfactant molecules for use with HFA propellants. As yet none of these research programs have successfully yielded molecules with suitable properties to control the suspension characteristics whilst also retaining a suitable toxicology profile.

An interesting alternative approach to suspension formulations in HFA propellants is via engineered drug substance particles. Porous drug substance/excipient particles can be produced via spray drying techniques. It is theoretically possible to match the density of the particles with that of the liquid propellant to produce a formulation with desirable suspension characteristics (19).

CONTAINERS

The essential requirements of containers used for MDIs are that they are compatible with the formulation, have an ability to withstand internal pressures up to 1500 kPa, and can be manufactured with reproducible quality. The most widely used containers for MDIs are made from an

Fig. 2 Types of aluminum cans used with MDIs.

aluminum alloy, although glass bottles have also been used. Aluminum containers (cans) are preferred due to their light weight, strength, break resistance, compactness, and ability to provide light protection. There are two main types of aluminum cans—the cut-edge can and the rolled-edge can (Fig. 2). The cut-edge can, which is most commonly used in the manufacture of MDIs, is manufactured by a deep-drawing process to leave a sharp edge to the can rim (Fig. 3). After formation, the cans are washed with solvent and aqueous detergent to remove residues of oil, which is used as a lubricant in the drawing process. Rolled-edge cans are formed by impact extrusion (slugging) of a slug of high purity aluminum. The excess material is trimmed off and the can neck is externally rolled. The deep-drawing process is preferred because the cans have a more uniform weight and wall thickness, which facilitates fill weight control during the MDI manufacturing process.

Although aluminum cans generally show good compatibility with the propellant systems used in MDIs, drug degradation or drug deposition on the internal walls of the can may require the use of internal coatings. A suitable epoxy resin or phenolic vinyl type coating may be used (25). More recently, low-surface-energy coatings based upon perfluoropolymers have been proposed for use with HFA propellant systems (26).

Fig. 3 Stages in the manufacture of aluminum cans by a deep-drawing process.

Glass bottles are not widely used because of their greater weight and potential fragility. Glass containers used with pressurized liquefied propellants are externally coated with a plasticized polyvinyl chloride (PVC) layer to retain glass fragments in the event of breakage. In the past, glass bottles may have been preferred for MDI formulations containing ethanol and CFC 11. Hydrogen chloride, formed via a free radical reaction, can result in corrosion of aluminum cans (27).

METERING VALVES: DESIGN AND FUNCTION

The primary function of the metering valve is to meter accurately and repeatably small volumes of the propellant-based formulation containing the drug. Secondly, it helps seal the pack to ensure minimal leakage of propellant. Most of the commercially available MDI products are fitted with metering valves designed to operate in the valve-down orientation, which eliminates the need for a dip tube. The typical MDI metering valve consists of two coupled valves placed on either side of a volumetric metering chamber (28). It is essential that during depression of the valve stem, the inner “valve” closes to isolate the container contents before the outer “valve” opens to allow discharge of the contents of the metering chamber. Reversal of this sequence would give rise to “continuous spraying,” placing the patient at risk of overdosage. The metering performance of the valve is a critical aspect of quality control. A diagrammatic representation of the sequence of operation of a metering valve is shown in Fig. 4.

A metering valve comprises a number of essential components (Fig. 5) having specific functions (Table 2). The most significant feature of the valve are the two seals or seats. These are separated by the metering chamber, which is created by the space between the stem, the body, and the seals. The cylindrical stem passes through the flat elastomeric seals to create a dynamic seal during movement of the stem along its axis. With the exception of the aluminum ferrule, all other components are either press-formed in stainless steel or injected-moulded in suitable plastics such as nylon, polyacetal, or polyester, which are dimensionally stable when in contact with the propellant. The stem return spring is invariably made in stainless steel. Good surface finish and careful dimensional control of all the components and their correct assembly are critical in ensuring satisfactory valve performance.

The valve is sealed against the container by a rubber flat cut or “O” ring gasket that is compressed by crimping the aluminum valve ferrule to the container neck.

Fig. 4 Operation of an aerosol valve.

Crimping during the filling operation is controlled by monitoring the crimp height and diameter to ensure adequate compression of the gasket. The optimum crimp parameters will permit correct valve function and minimize propellant leakage.

ELASTOMER COMPONENTS

The elastomeric sealing components of the metering valve are particularly critical. In those valves used with CFC propellants, the elastomeric seals have typically been formed from an acrylonitrile/butadiene rubber, which has been cured with sulfur. These rubber seals may not be fully

Fig. 5 Components of a metering valve.

compatible with HFA propellants; hence, alternative elastomeric materials have been used. These materials include peroxide-cured acrylonitrile/butadiene, ethylene-propylene diene monomer (EPDM), and chloroprene and thermoplastic elastomers (TPE). The elastomeric materials used to form the dynamic seals around the stem and the static gasket seal between the can and valve may differ based on the required properties of the rubber for the specific function of the seal (29). The most important characteristics of the elastomeric seals include their composition and degree of curing, which control the physical properties and swelling characteristics in situ, compatibility with the propellant and drug, their affinity for drug absorption, their dimensions and surface finish, and their potential to release foreign particulate matter and extractable material. The solvency properties of both CFC and HFA propellants is such that low levels of extractives from the elastomers can appear in the MDI formulation during storage. These may not present any safety concerns and their levels can be further minimized by using solvent-extracted elastomeric seals. The elastomeric seal material may also be selected, in part, to influence other changes that can occur during storage of an MDI. Under normal storage conditions, moisture will diffuse through the elastomeric seals into the MDI contents. The rate and quantity is dependent on the environmental conditions and the nature of the elastomeric material, the water vapor transmission properties of which can differ significantly (30).

Propellant leakage from an MDI is characteristic of this product and occurs by diffusion through both stem seals

Table 2 Function of the valve components

Valve component	Function
Gasket	Seal between the valve and can; usually made of rubber.
Ferrule	An aluminum cup that holds the valve components together and attaches them to the can in the crimping process.
Stem	Moving part of the valve that provides the metering action and connects the valve to the actuator. Its design provides entry and exit ports to the metering chamber to permit filling and discharge of the metered dose respectively.
Seat	Provides the main seal around the valve stem and is usually made from rubber. Most valves have two seats to provide the metering action.
Spring	Returns and holds the stem of the valve in the rest position after actuation. May be located inside or outside of the metering chamber.
Metering chamber	Defines the volumes of liquid discharged. Valves with 25-, 50-, 63-, and 100- μ l nominal metering volumes are available.

and gasket of the valve. The leakage rate increases with increase in environmental temperature, and tends to parallel the rubber swell for a particular propellant–rubber combination. Propellant leakage from an MDI may shorten the product shelf-life by raising the drug concentration of the liquid contents, thereby increasing the metered dose of medicament. Additionally, excessive leakage may prevent the labelled number of actuations being delivered by the MDI.

ACTUATORS AND SPACERS

Overview of the Components for the Basic MDI Actuator

For a simple MDI, the actuator is a one-piece plastic molding that performs a number of critical functions as a key packaging component in the overall system. The main plastic body of the actuator surrounds and protects the aerosol canister, and veins within the actuator help to locate the canister so that when it is depressed by the patient to release the dose, the canister moves straight down without flexing the valve stem. A high degree of flex could result in

**Fig. 6** Typical MDI actuators.

poor performance, e.g., as a result of continuous spraying of the valve. The veins also serve to centrally locate the canister within the actuator body to create airflow paths with minimum resistance so that air can be easily drawn through the device as the patient inhales (67). Some typical MDI actuators are shown in Fig. 6.

The actuator also incorporates the stem block containing the spray nozzle. The stem block contains a socket that the valve stem pushes into when the canister is placed inside the actuator. The socket is designed to provide a tight interference fit with the valve stem such that there is no tendency for the canister to fall out of the actuator on transportation and also so that the complete dose is pushed out of the spray orifice and does not leak back up the side of the valve stem to deposit on the valve ferrule. The final critical component of the actuator is the mouthpiece. The design of this component needs to be such that the patient is easily able to form a seal around it to draw air through the device and inhale the dose. The mouthpiece should also be designed to minimize the extent of drug deposition on the actuator during dose delivery. Typically, 10% to 20% of the dose delivered from the valve is deposited on the actuator and is therefore not available for delivery to the patient. Mouthpiece designs are usually a compromise of what is cheap and easy to mold, what is easy for the patient to use and form a seal around, and what will result in a small and portable device with acceptable drug delivery characteristics. A huge advantage to the MDI is that it is small, light, easy to carry, and discrete to use. A large and complicated design optimizing the delivery characteristics would probably be expensive for the manufacturer and unattractive to patients. A further component of most MDI actuator designs is a dust cap. This is most usually a separate plastic molding that

Fig. 7 Detailed diagram of MDI actuator stem block.

snap-fits onto the main actuator body. The main purpose of the dust cap is to prevent foreign matter from entering the mouthpiece and valve stem area while the device is being transported. Foreign matter in this area could either be inhaled by the patient during use or could potentially block the spray nozzle. A detailed cut-away drawing of a typical actuator stem block is shown in Fig. 7.

For a simple MDI actuator, the spray nozzle and valve stem socket are formed by metal pins that enter the stem block as part of the actuator molding process. It is essential to retain accurate dimensional control for these critical areas, to ensure absence of leakage and correct and consistent spray performance during discharge. Various combinations of nozzle diameter and length and expansion chamber volume (volume between the metering chamber and the actual spray nozzle, principally the internal volume of the valve stem), have been investigated. In practice, nozzle diameters range between 0.2 and 0.5 mm. Small nozzle diameters tend to give higher fine particle masses but also increase the length of time it takes to deliver the dose and can be more prone to blocking (31). The actuator parameters cannot be optimized in isolation but must be designed to work in harmony with a specific metering valve, container, and formulation combination (32).

Spacers

As mentioned earlier, the simplest MDI actuators are a compromise between portability, cost, and performance. When a simple MDI is used, a significant portion of the dose is deposited in the oropharyngeal cavity. This is because when the canister is pushed down for the dose to be delivered, the spray emerges from the actuator orifice at such a rate that there is insufficient space for the cloud to decelerate before it strikes the back of the throat or other parts of the oropharyngeal cavity. Simple low-volume spacer devices (70–150 ml) provide an extension to the mouthpiece to allow space for the deceleration of the

aerosol cloud to occur. These can either push-fit onto the simple classical type of actuator or can unfold as part of an integral actuator/spacer design (33–37). They significantly reduce the amount drug deposition in the oropharyngeal cavity (35) by allowing more time for the aerosol to decelerate. As a consequence, slightly more drug may be deposited in the lungs but the majority of the reduced throat deposition is accounted for by higher device/spacer deposition. The principal benefit in using this type of simple spacer is in reducing oropharyngeal irritation and hoarseness caused by the deposition of inhaled steroids (34, 38).

Spacer/Holding Chambers

In addition to the simple spacer devices that have been described, there are also much larger volume spacer devices (500–750 ml). These devices provide all the benefits of the simple devices but are capable of capturing and holding the dose prior to the patient inhaling. A one-way valve (or paired valves) may also be incorporated into the mouthpiece region to allow natural breathing cycles so that the patient breathes out into the atmosphere but breathes in through the spacer to inhale the dose held within the spacer. These larger spacers may be beneficial for asthmatic patients who show poor coordination of inhalation with inhaler actuation (33, 34) because actuating the canister to deliver the dose does not have to be coordinated with breathing in (39, 40). Drug deposition in a spacer increases with decreasing chamber size (as a function of width and length) (35, 36). Spacer deposition may be influenced by the size of the metering valve and the propellant composition (37). The delivery of a respirable drug from MDIs is generally similar with or without a larger spacer but with the advantages of lower oropharyngeal deposition and lower need for accurate coordination.

The materials used to manufacture spacers are also key to their performance. A build-up of static electricity on a spacer device can significantly affect the amount of drug deposited on it and, consequently, the dose the patient could receive (41). Similarly, the way in which spacer devices are washed or dried can also result in a build-up of static electricity (42).

BREATH OPERATED INHALERS AND OTHER DEVICE ENHANCEMENTS

The MDI has proved itself over many years of successful use as a highly effective method for delivering drug to the

lungs for the treatment of respiratory disease. The MDI is simple to use for most people, but there are difficulties that certain sectors of the patient population may have with the use of this device type.

Very young children and older people have significant difficulty coordinating their actuation of the device with breathing in (43). Patients who have this coordination difficulty can either be supplied with a dry powder inhaler (where the inspiration through the device is also responsible for the release and aerosolization of the powdered drug so that coordination is no longer an issue), or they may be prescribed a Breath Operated Inhaler (BOI).

Several of these device types are marketed; they are still MDIs but the device takes over the responsibility for actuating the can as the patient breathes in. Typically, the device is primed immediately before the patients takes their dose. This priming can be achieved either via the opening of the dust cap to reveal the mouthpiece or by operating a special priming lever. For the currently marketed devices, this results in a spring being compressed above the aerosol canister that has enough strength to actuate the can on release. The device contains a triggering mechanism that is released when the patients breathe in through the device to take their medicine. The release of the triggering mechanism allows the coiled spring to push the MDI canister down and deliver the medicine, negating the need for the patients to coordinate the activities (44). Although there is significant merit to devices of this type, they need to be carefully developed to ensure that the altered pattern of use in terms of priming, shaking, and taking the medicine works in harmony with the other device components to ensure that consistent doses of medicine are always delivered from the device.

More BOI devices are likely to reach the market. They could be either mechanical or electronic in operation. The incorporation of electronics into a device of this type opens up the possibility of including other patient features, e.g., counters and other data logging.

MDI COUNTERS

One significant issue with MDIs is that because of the aluminum canister used for most device types, it is impossible for the patient to know exactly how much medicine is left in the inhaler. Shaking the canister prior to taking the medicine can give the patient some confidence that formulation is still there within the device, but this is a very crude measure. MDIs are always filled with more medicine (termed the overfill) than the number of actuations mentioned on the label. Thus a 200 actuation

product might actually be filled with 240 actuations. There are a number of reasons for this:

1. There is always some leakage from devices of this type throughout their life. Including an overfill guarantees that the device is still capable of delivering the claimed number of actuations at the end of the shelf life.
2. There can be some variability in the dosing performance of an MDI as the formulation level becomes very low. Including an overfill guarantees that the MDI will perform consistently throughout the number of actuations claimed on the label.
3. There is a portion of the formulation that is not removable from the canister because of the positioning of the metering valve sampling port.

Using a glass container is one method of overcoming the difficulty by knowing how much medicine is left, but because of the overfill factor there will always appear to be medicine left even after the patient has exceeded the number of actuations claimed on the label. Also, glass containers may be more bulky than their aluminum counterparts and are certainly more expensive to produce.

The alternative to a transparent container is to fit the MDI with some kind of actuation counter or level indicator. The level indicator, much like the fuel gauge within a car, will give some idea of the amount of medicine that remains, but will not be an exact measure. A numerical counter is probably the preferred solution as it leaves the patient in absolutely no doubt about the amount of medicine remaining in the device. When the number of actuations claimed in the label have been taken from the device, the patient will know that a replacement is needed, thereby completely avoiding the uncertainty that would arise from continuing to use the device during the overfill phase between label claim and final device exhaustion. The counting mechanism could be either applied to the top of the aerosol canister or the valve area or be an integral part of the actuator and be mechanical or electronic in operation.

OTHER DEVICE ENHANCEMENTS

The incorporation of breath activation and/or counting mechanisms into the MDI opens the possibility of including other device features, particularly if the above-mentioned two features are achieved via electronic means. MDIs that feature data gathering technology allow the patient or physician to monitor how and when the medicine is being taken (compliance) or to monitor lung function and control the amount of medicine that the patient is taking are distinct possibilities.

Spray Atomization and Evaporation

The respirable fraction or Fine Particle Mass (FPM) of a finely aerosolized drug delivered from an MDI is highly dependent on the atomization of the formulation and the subsequent spray dynamics. The aerosol characteristics depend heavily on interactions between the propellant(s), the (typically) micronized drug particles, the formulation excipients, and the design and dimensions of the metering valve and the key actuator variables (stem block, atomization orifice, actuator airflow paths, and mouthpiece design). The importance of these inhaler variables has been demonstrated previously (45–47). MDIs give a much slower metered delivery and a much finer spray droplet size distribution than what would be expected for simple hydraulic atomization because a mixture of gas and liquid is discharged from the metering chamber.

Partial flash evaporation of the propellant occurs in the metering chamber and in the expansion spaces of the valve stem and actuator stem block (47). Further evaporation also occurs within the discharge nozzle, and alternating segments of liquid and gas pass through the nozzle in a process of effervescent atomization.

The spray droplets are ejected at a high velocity of about 25–30 m/s (48), and although the aerosol decelerates rapidly the velocity is still much higher than the inhaled air velocity, resulting in significant drug impaction in the oropharyngeal region. This effect has been mimicked crudely in simple throat models (49) and more accurately in throat models having carefully matched human dimensions (50).

The probability of oropharyngeal deposition is determined more by droplet size than by velocity and density because the particle inertia is proportional to the density, velocity, and the square of the diameter. It, therefore, follows that oropharyngeal drug deposition is reduced and the respirable drug delivery is increased when MDI sprays are finely atomized and evaporate rapidly. Such MDI sprays are generally promoted by increasing the propellant vapor pressure (45, 47, 51) and reducing the actuator spray nozzle diameter (45, 46, 52).

Spray evaporation is impeded by the inclusion of appreciable concentrations of nonvolatile miscible excipients in the formulation. These include ethanol as a cosolvent (53), and CFC 11, both having low volatility in the spray, which is also chilled by propellant evaporation, thereby further reducing the rate of evaporation. The particle size distribution of the resulting aerosol depends not only on the spray dynamics but also on the number and primary size distribution of the drug particles in liquid suspension and their degree of deagglomeration during

spray atomization. The evaporated aerosol particle size increases with the concentration of drug (45, 54) and nonvolatile excipients (45, 55) in suspension formulations and also in solution products.

MANUFACTURING

In the manufacture of MDIs, liquid filling procedures have been developed based on either a cold-filling method or a pressure-filling method. Both methods are suitable for either solution or suspension formulations and regardless of the process, it is important to maintain a low atmospheric relative humidity in the filling area to minimize condensation and possible absorption of water by the product.

The cold-filling process involves chilling the propellant and drug formulation to approximately -60°C in tanks to maintain the liquid state and metering it into the open cans in a single step. The cans are then sealed immediately by crimping on the valves.

The potential advantages of this procedure are that it is simple and can accommodate any valve, with minimal changes to the production line. The potential disadvantages include high energy consumption (refrigeration), inconsistent fill weights due to propellant evaporation, contamination from moisture condensation, and possible irreversible physical changes in the formulation at low temperature.

The pressure-filling process is now more commonly used and relies on the injection of at least part of the fill through the valve, which is crimped to the container. Pressure filling with CFC propellants generally involves preparing a concentrated suspension (or solution) of the drug in the high-boiling CFC 11, together with any excipients. This concentrate is metered into the open container in a cool area to minimize evaporative losses of propellant before crimping on the valve. The low-boiling propellant, CFC 12 or a CFC 12/CFC 114 blend, is then filled through the valve by high-pressure injection, a process commonly known as gassing. For this process, the potential advantages are that accurate fill weights are achievable and that filling can be undertaken at or near room temperature. The potential disadvantages are that the filling equipment is complex and expensive to install and that the valves must be suitable for pressure filling.

With the transition to HFA/HFC propellants, the lack of a direct replacement for CFC 11 has resulted in the development of a single-stage pressure-filling process. For the HFA/HFC propellants, a concentrated suspension (or solution) of drug is prepared in the propellant

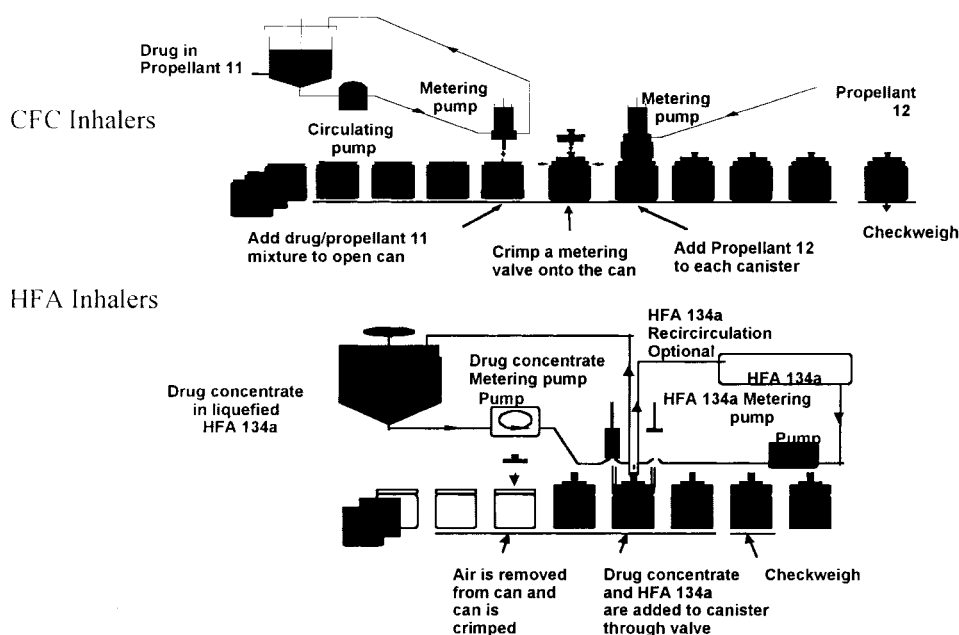

Fig. 8 Production pressure-filling sequence for MDI cans.

(134a or 227ea) contained in a pressurized system. A valve is crimped to a container and the concentrate is pressure-filled through the valve, followed by an aliquot of pure propellant (56). Such a process requires the development of a total pressurized filling system with compatible elastomeric seals and the use of pumps capable of recirculating, without cavitation, high-pressure liquids.

During the filling process, it is normal to displace the air from the container before valve crimping to avoid internal pressure changes in the MDI at the time of progressive discharge of the contents during use. For the cold filling and two-stage pressure-filling processes, air displacement occurs after filling the initial propellant liquid into the container. However, in the single-stage pressure-filling process, air is purged from the container in a separate operation prior to crimping the valve, using either a small injection of propellant or vacuum (Fig. 8).

High-speed rotary filling machines are widely used to provide concentrate filling, valve placement, and crimping and gassing in a continuous sequence. Similar set-ups are used for HFA/HFC MDIs with appropriate modifications to permit container purging. Intermittent indexing machines are often employed for small-scale filling. Filling lines may also be equipped with a checkweighing station to reject any over- or under-filled canisters. In addition, a heat-stressing facility may be employed after filling to raise the temperature of the MDIs to a predetermined value (e.g., 50–55°C) to increase the

internal pressure and thereby challenge the integrity of the crimp seal. After a defined quarantine period, further checkweighing, normally as part of the final packaging operation, can be used to reject canisters that have leaked.

QUALITY CONTROL

Quality control testing of MDI batches is applied to the individual inhaler components prior to manufacture, as in-process controls during the manufacturing, and to the finished product (Table 1). A number of publications describe quality control procedures for MDIs (21, 57, 58).

Component and In-Process Quality Control

Typical QC procedures for the aluminum canisters would include careful assessments of their dimensions, weight, strength, surface finish, and cleanliness. Important canister characteristics are neck finish and dimensions, regional can wall thickness, and external size of the canister, which influence valve sealing, canister strength and volume, and the fit into the actuator. Canister strength is typically monitored by the manufacturer, using a hydraulic pressure test. Glass bottles may be subjected to impact fracture drop tests.

The metering valve is generally the most critical inhaler component in terms of its effect on product performance;

Table 3 Quality control and analytical tests for the characterization of metered dose inhalers

Name of test/test area	Type of data/comments
<i>Individual component testing prior to manufacture of active product:</i>	
Containers	Dimensional accuracy and surface quality; strength testing by canister manufacturer
Metering valves	Dimensional accuracy and surface quality of individual components from dismantled valves
Mean weight per actuation and leakage rate	Samples filled on the production line and shot weight through use data generated to guarantee correct valve function; samples tested after a period of equilibration to ensure leak rates within specification
Input micronized drug	Chemical, physical, and particle size specifications
Propellant	Chemical and physical specifications
Surfactant	Chemical specification
Actuators	Dimensional accuracy and finish; accuracy and centralization of the atomization orifice
<i>In-process control testing that occurs during manufacture:</i>	
Atmospheric conditions	Monitoring of atmospheric temperature and humidity in manufacturing areas
Drug suspension concentration	Rapid analysis initially and during filling
Drug suspension	Periodic fill weight checks (if separate suspension followed by gassing)
Filled canisters	Automatically checkweigh all canisters
Gross leakage and safety	Containers heated to raise internal pressure; visible leakage and pack distortion examination
Control of leakage rate	Checkweigh all containers after a suitable quarantine period to meet specified limits
Metering-valve function	Each filled container is spray-tested after quarantine, following a number of priming actuations
<i>Analytical testing applied to completed product:</i>	
Appearance	Description of the suspension; absence of corrosion of canister; completeness of inhaler components
Identity	HPLC or infrared confirmation of identity and absence of polymorph or incorrect solvate
Microbial limit testing	e.g., to USP requirements
Spray pattern	Consistent, concentric pattern fired straight with respect to mouthpiece geometry
Water content	Karl Fischer or similar method
Foreign particulate matter	BP 1993
Leachables	Consistent profile between batches, careful consideration of levels versus specifications based on individual components
Pressure test	USP
Leak test	USP
Drug related impurities	Comparison with specifications based on preclinical/clinical batches
<i>Characterization of particle size distribution:</i>	
Multistage impactor	Careful consideration of particle size distribution profile data and a multipoint specification; individual stage data may be combined for comparison with the specification for QC purposes
Laser particle sizing	Tends to be used to characterize products more in development
Microscopy	Tends to be used to characterize products more in development
Characterization of drug delivered from the MDI	
Mean dose delivered and content uniformity	Careful consideration against various specifications covering mean and individual actuations through use assessing inter- and intracan variability; regulatory guidance varies from region to region (see Refs. 22, 58, 59)
Number of primes	Test to demonstrate the number of priming actuations the patient must fire to waste before performance is nominal
Number of actuations	To demonstrate that the product delivers nominal dose at the end of label claim (can be derived from CU data)
Actuator deposition	Generated during development to determine how much drug deposits on the actuator with each dose and thus what the ex-actuator dose is

therefore, it also requires detailed testing prior to use. The disassembled valve components are examined for dimensional accuracy and surface quality. Assembled valves are tested for correct metering function and formulation delivery. Test packs are stored until equilibration and the units are tested for propellant leakage (weight loss) and weight of metered delivery. The reproducibility of delivery has been reported for various valve propellant combinations (59). Where propellant mixtures are used in the product, there is some progressive fractionation during discharge of the pack contents because of greater loss of the more volatile component (59). The associated change in liquid propellant density can cause a small progressive change in metered delivery weights, but this does not influence the drug delivery, which is determined by the metered volume.

Common in-process control procedures for MDIs are provided in Table 3. In addition, stringent environmental controls are required for air cleanliness, humidity, and temperature during the manufacturing run. Rapid verification of the drug content of the fresh bulk suspension or solution may be important prior to commencing the filling run because reworking of aerosol products for recovery is not practical. It may be necessary to monitor the dispersion quality and drug concentration of suspension during filling. Various online monitoring methodologies are under development but still the principal method is via measuring the total drug per can for a sample taken from the manufacturing run. Inline checkweighing of the crimped units provides an indirect record of the suspension fill weight per canister.

MDI BATCH ACCEPTANCE

MDI products are subject to batch control and acceptance tests similar to those for other pharmaceutical dosage forms, that is, active drug identification, dose delivery, and dose uniformity. Additional special tests unique to inhalers, e.g., characterizing the particle size distribution of the delivered aerosol, are also applied. Typical tests are shown in Table 3.

It is now rare to specify determination of the metered drug delivery by discharging directly from the metering valve (without the actuator) into a solvent (60). Via this route, correction is subsequently made for the amount of drug that typically deposits on the actuator to leave the ex-device dose available to the patient. The preferred method now is to discharge the inhaler with the actuator fitted, into a trapping system with an airflow being drawn through it (e.g., the USP/NF method) (61). This method of

characterizing the ex-actuator dose is much more representative of the real patient case. Typically, the mean specified delivery ex-actuator is controlled to within 85–115% of the label claim, with additional limits also applied to the spread of individual doses.

PARTICLE SIZE ANALYSIS OF SPRAYS AND AEROSOLS

The characterization and quality control of the particle size distribution of the discharged aerosol has become one of the key tests applied to MDI and other inhaler products, and a wide variety of methods have been developed to make this possible. The available methods can be broadly split into two categories: optical (typically laser) methods or methods based on inertial impaction.

Optical methods typically have the advantage of producing detailed results very quickly on a small number of actuations, but the disadvantage is that they do not characterize the whole spray emerging from the device. They are also not able to distinguish drug particles from drug-free excipient particles or propellant alone droplets or even between two different drug substances as in the case of a combination product. The sizing results obtained via optical methods may give an incorrect or biased impression of the true particle size distribution for the pharmaceutically active substance. Nevertheless, these methods can prove to be extremely useful from a qualitative perspective.

SPRAY DROPLET SIZE ANALYSIS

The spray droplet size distribution has a major influence on the amount of oropharyngeal deposition and the amount of drug delivered to the lungs and the regions of lung deposition. Methods for spray droplet particle sizing from MDIs (4, 6) have been reviewed.

For the quality control of actuators, spray flume appearance and profile are often used (62). These methods potentially highlight any gross issues with the moulding of the actuator atomization orifice and stem block (e.g., firing off-centre or poor spray homogeneity). Flume profiles can also be obtained by timed flash photography (4, 63), but an even better picture of dynamic flume changes can be provided by high-speed video recording (62, 64).

Spray droplets have also been analyzed microscopically after impacting the spray on to specially coated slides. Microscopic laser holography has been used to measure droplet size distributions and concentrations for MDIs

(65). Laser video imaging has also been applied to MDI sprays (66).

Laser diffraction (LD) size analysis is a rapid and convenient noninvasive method used extensively for measuring the droplet size distribution of industrial sprays. LD analysis has been used for nonmetered dispenser sprays to study the effects of varying the propellants (67, 68) and valve orifices (69).

Oropharyngeal spray impaction depends on the droplet velocity and size. Both these parameters can be measured simultaneously and recorded for each droplet. With Phase Doppler Anemometer (PDA) instruments, useful results have been obtained on MDI sprays (70).

MDI AEROSOL PARTICLE SIZE DISTRIBUTION ANALYSIS

Methods for the size analysis of MDI aerosols have been reviewed (6, 71–73). Various sizing methods are available. Microscopic examination of particles based on discharging the spray against a slide (72, 73) can provide a limit test for unduly large single particles resulting from poor micronization or poor physical stability of the drug in liquid suspension, but this is only a very gross measure.

INERTIAL IMPACTORS

Inertial impactors fractionate aerosol particles aerodynamically according to their inertia, which increases with size. Inertial impaction is the most widely used method for sizing MDI aerosols, partly because a large sample is measured, consisting of the total aerosol generated from a number of actuations. Methods of this type have the advantage that the aerodynamic measurement accounts for the effects of particle shape and density and that the aerodynamic size distribution is measured specifically in terms of the drug mass independently of any other aerosolized constituents that may be present, giving a specific measure of the aerodynamic size distribution of the drug.

The most commonly used tool for the aerodynamic classification of particle size distributions is the Andersen cascade impactor. The Andersen impactor was originally developed for the environmental monitoring of air samples but is now commonly applied to characterizing medical aerosol size distributions. Particle size distribution profile data can be generated or an overall figure can be derived to loosely determine the mass of drug that falls into the respirable range. This is achieved by combining several impactor stages with particle size cut-offs roughly

corresponding to respirable particles (74). To gather the particle size distribution data, the MDI is actuated a number of times into the cascade impaction apparatus via a connecting elbow (termed the throat or induction port). On entering the impactor, the aerosol is passed through successive impaction plates with decreasing jet diameters. Velocities increase as the particles go down through the impactor to the point where they impact on the collection plate below. Cascade impactors (particularly the Andersen) have been used extensively to assess MDI aerosols (72). A schematic diagram of the Andersen impactor is given in Fig. 9.

To collect and deliver the MDI discharge to the impactor, two main types of collector system have been used: a large chamber to permit extensive or complete spray droplet evaporation before impaction (72, 75, 76), and a restrictive induction port (51, 73, 78) in which considerable droplet impaction occurs in a very crude analogy to the behavior for the human oropharynx. The extent of droplet evaporation before impaction, and therefore the size distribution measured, is a function of the lag time between spray discharge and impaction. The lag time depends on the size and shape of the particular inlet duct and upper impactor stages and also the volumetric airflow rate. The droplet evaporation rate depends on the volatility of the particular propellant/excipient system (75) and the effect of the airflow rate and air vapor mixing on vapor diffusion from the droplets. Clearly, it is essential in comparing inhaler systems to standardize the induction port, cascade impactor, and airflow rate (72, 77).

Fig. 9 Schematic representation of the Andersen cascade impactor.

The impacted drug fractions are normally measured via a specific chemical assay, although microweighing the plates has also been investigated (75, 78). A number of actuations are normally accumulated for each cascade impaction determination to collect sufficient drug for accurate assay. The United States Pharmacopoeia includes a test for MDIs, using a cascade impactor coupled to a throat of specified dimensions (74).

Simple two-stage impactors (or impingers) with a defined throat geometry have also been used to generate simple data more rapidly than for the multi-stage cascade impactors (or impingers) or for QC purposes (74, 79–81). The Twin Impinger (TI) has gradually become a much less widely used technique as it cannot provide the more detailed distribution data required for in-house product development or by the regulatory authorities, but it can be sensitive enough to reveal formulations that are unstable due to crystal growth or particle aggregation.

SINGLE PARTICLE OPTICAL SIZERS (SPOS)

Single particle optical sizers measure each aerosol particle passing through a small optical sensing zone to give rapid “real time” measurement of particle number diameter distribution and concentration. Low particle concentrations are necessary to avoid coincidence errors arising from multiple particle occupancy in the sensing zone. SPOS methods are rapid, but they have the following disadvantages for MDI aerosol evaluation:

- Drug containing particles are not distinguished from excipient or foreign particles.
- Aerosol sampling may not be representative due to inadequate measurement of the large particles and their possible partial loss in the sampling probe (82).
- Equivalent mass distribution is derived based on the assumption that the particles are spherical and of equal density.

Optical single-particle counters offer much more rapid aerosol size analysis than do impaction methods. They need to be applied with caution to MDIs for the reasons stated previously.

Metabolite Identification in Drug Discovery

Kathleen Cox
Nigel Clarke
Diane Rindgen

Schering-Plough Research Institute, Kenilworth, New Jersey, U.S.A.

INTRODUCTION

The challenge in modern drug discovery is not only to rapidly screen through large number of potential lead drug candidates, but also to find out as much information about these compounds as possible. Since a high percentage of drugs fail in the preclinical and clinical phases of development after millions of dollars have been invested, this methodology is economical, and will hopefully move only lead drug candidates with the highest possibility for success forward for development. Many drug metabolism and pharmacokinetic assays have adapted readily to the discovery environment and are used as routine screens.^[1] In vitro methodologies such as Caco2 cell-based assays,^[2] CYP450 enzyme inhibition assays,^[3,4] and microsomal^[5] or hepatocyte incubations have been particularly useful in screening large numbers of compounds for absorption, inhibition of the common metabolizing enzymes, and metabolic stability, respectively. In vivo assays are typically less amenable to high throughput, but have come to the forefront in drug discovery because of the wealth of drug metabolism and pharmacokinetic information that can be obtained from them. Novel dosing procedures such as cassette, or N-in-one dosing,^[6,7] involve dosing large numbers of compounds in a single animal for screening purposes. The drawback of this type of experiment is the risk of drug–drug interactions. Alternatives to the cassette dosing procedure include sample pooling prior to analysis,^[8,9] which achieves the goal of higher throughput without compromising the pharmacokinetic evaluation of the drugs.

While metabolite identification studies provide critical information on drug candidates, these studies have typically been reserved for compounds late in the development phase. These studies are not amenable to high throughput as each compound will give a different metabolic profile, and evaluation of the data can be a lengthy and labor-intensive process. Traditional studies required radio labeled compounds, synthetic standards of potential metabolites, and sophisticated analytical instrumentation.

However, with the recent advances in analytical technology and software programs, metabolite identification studies are now playing a pivotal role in the discovery phase of new drug entities. Early identification of metabolic “hot spots” in a particular structural series provides valuable information to the medicinal chemists and can drive the progression of chemical structures in a particular therapeutic program. In addition, early characterization of potentially active or toxic metabolites can direct a program to more potent and safe recommendation candidates.^[10] This article provides an overview of the value that early metabolite identification studies can give to a discovery program. Analytical techniques, available in the discovery phase, are described for the early characterization of metabolites, focussing on the use of liquid chromatography-tandem mass spectrometry (LC-MS/MS), and the advances in software programs to aid the analyst in critically and rapidly evaluating the data produced. The focus is on small molecule applications.

METABOLISM AND DRUG DESIGN

Many drug candidates fail early in the development phase due to poor pharmacokinetics, such as their half-life being too long or too short, high clearance, or extensive first pass metabolism.^[11] An early evaluation of the metabolic fate of these compounds can be invaluable to the program. Typically, the compounds under investigation in the discovery phase of a specific program are very similar in structure. Medicinal chemists are searching for structure–activity relationships and a final compound is chosen by fine tuning the structure of interest for best selectivity, activity, and overall pharmacokinetic profile. Since structures are similar, it is often possible to determine specific portions of the molecule that are particularly susceptible to metabolic alteration. These structural characteristics can either be tailored into future molecules to shorten a lengthy half-life or tailored out of future molecules to lengthen a short half-life.

Another advantage of evaluating similar compounds in a structural series is the often predictable nature of the metabolic alterations. The analyst can quickly determine the most common metabolic alterations to a specific structure, and understand any novel or unexpected metabolic modifications. A fairly high throughput screening protocol can then be put into place to quickly evaluate all future compounds within the structural series for those specific metabolic alterations.^[12] This is particularly useful in screening for toxic metabolites such as acyl glucuronide or glutathione conjugates. In these cases, it is only necessary to know the mass of the metabolic alteration and the mass spectrometer can then rapidly evaluate samples generated from *in vivo* or *in vitro* studies for those metabolites. The generation of acyl glucuronide metabolites *in vitro* has been useful in evaluating the extent of formation, thus giving an idea of toxic liability.^[13,14] This assay is also amenable to a high throughput format. Such an *in vitro* approach has also been extended to investigate the stability of acyl glucuronides, again providing an idea of reactivity and potential toxicity.^[15] In this manner, early metabolic screening can play a pivotal role in driving the drug design of discovery compounds.

SPECIES DIFFERENCES IN METABOLISM (METABOLIC PROFILING)

All mammals exhibit differences in their biochemical make-up between species and sometimes even sex, particularly in the structures and activities of their cytochrome P450 metabolizing enzymes.^[16] Because of these differences, both the rate of drug metabolism and the metabolic profile may differ between animal species. It is possible in drug discovery to obtain an early look at the human metabolism of drug candidates through *in vitro* systems such as microsomes, hepatocytes,^[17] S9 fractions, and liver slices. It is, therefore, important to determine whether the human *in vitro* systems produce any unique metabolites, not expressed in other animal species. This is due to the critical importance during preclinical development that adequate exposure to all metabolites is achieved in the animal safety studies to ensure the validity of the clinical studies. Although *in vitro* systems are not always accurate predictors of *in vivo* metabolism, particularly in the case of humans, it is useful to see what metabolic pathways can be accessed in a human system and make sure that the metabolites thus produced are also generated in an animal system.

METABOLITE CHARACTERIZATION VS. IDENTIFICATION

Definitive metabolite identification studies require absolute structural identification of each metabolite produced. This is a labor-intensive process requiring separation of all metabolites produced in a particular biological matrix (i.e., bile, urine, plasma), analytical characterization of the structure of the metabolite, and confirmation with a synthetic standard. This methodology involves the evaluation of one metabolite after another in a serial fashion. Often the structure of a metabolite can be elucidated by mass spectrometry using exact mass measurements to obtain an empirical formula and/or obtaining a detailed fragmentation pathway for the metabolite. However, the most definitive technique for structural elucidation is NMR. This technique can not only determine the exact site of modification, but also the stereochemistry of the metabolite structure. The drawback of using NMR is that it typically requires a large amount of the metabolite in order to provide definitive structural data (micrograms) while LC-MS/MS typically requires nanograms or even picograms of material for structural characterization. While this kind of detailed analysis is required once a compound has progressed to the development stage, it is not required in drug discovery. Often, at this stage, it is sufficient to merely know the portion of the molecule that is metabolically labile. Furthermore, this approach does not require the systematic isolation and purification of each metabolite produced and, in fact, can be conducted in more of a parallel manner, evaluating all metabolites from a single sample within one chromatographic separation.

INSTRUMENTATION

High performance liquid chromatography coupled with tandem mass spectrometry (HPLC-MS/MS) is an analytical technique that is ideally suited for metabolite characterization.^[18,19] The chromatographic conditions are sufficient to separate the analyte and metabolites from the background, and the mass spectrometer is a selective and sensitive detector, capable of characterizing low levels of metabolites in complex biological matrices. There are a variety of mass spectrometers available and each possesses unique capabilities and advantages in the characterization of metabolites. The use of several complementary LC-MS/MS systems is the most stringent way to provide complete characterization of metabolites.

The triple quadrupole mass spectrometer is generally considered as the most versatile of all tandem MS instruments and is useful in the initial evaluation of metabolites

for a new compound.^[20–22] Several types of tandem MS experiments can be performed, requiring no previous knowledge of a compound's metabolites. They only require a synthetic standard of the starting drug compound. This compound, once ionized and passed into the collision chamber of the triple quadrupole mass spectrometer, will fragment into pieces upon energized collisions with gas molecules. This fragmentation is characteristic of the structure of the compound, and, as many of the metabolites typically have similar structural features to the parent compound, the metabolites will often dissociate into some of these same structural fragments. The triple quadrupole mass spectrometer is capable of performing a precursor ion scan experiment in which all ions are passed into the collision chamber and are dissociated into fragments. The fragments are then passed into a different chamber of the mass spectrometer and evaluated. A fragment, that is the same as that produced by the original drug compound, can be linked back to its originating ion (i.e., the metabolite). In this manner, the mass of the metabolite can be determined along with some information about the structure. This is a fairly selective scanning process so matrix or background ions will not contain structural features similar to the parent drug and will not be detected. A second, similar scanning technique can search for neutral portions of potential metabolites after dissociation in the collision chamber. This is a highly useful experiment since conjugated metabolites, such as glutathione, glucuronide, and sulfate conjugates, give characteristic neutral losses in the collision chamber. This experiment, called a constant neutral loss scan experiment, is so generic that it does not even require any prior knowledge of the parent drug. The precursor and constant neutral loss experiments can be performed within the LC timeframe required for metabolite identification experiments.^[23] Once a putative metabolite is discovered in these scanning experiments, it can be confirmed and further characterized by a third scanning technique called a product ion scan experiment. A product ion scan allows only the ion of the prospective metabolite to pass into the collision chamber. The metabolite dissociates into fragments characteristic of its structure, some fragments similar to the parent drug compound, and some different. A comparison of the product ion spectrum of the putative metabolite with the parent drug can provide a great deal of information about the metabolic alteration and structure of the metabolite.

Often these types of experiments can point to the portion of the drug that has been metabolically altered, rather than completely identify the structure of the metabolite itself. However, as mentioned previously, this is often enough in the discovery phase to alert the structural chemists to the metabolically labile portion of the

molecule, but sometimes further experiments are necessary to narrow the site and nature of the metabolic alteration.

A second type of MS instrument capable of performing a product ion scanning experiment is the ion trap mass spectrometer. The difference between this instrument and the triple quadrupole mass spectrometer is the ion trap is capable of performing numerous sequential product ion experiments on the same compound. For example, a potential metabolite is dissociated into several characteristic fragment ions in the first stage of MS/MS. Then, one of these fragment ions can be further dissociated into smaller ions. This is a second stage of MS/MS known as MS³. This process can continue (MSⁿ)^[24,25] until the site of metabolic alteration is determined or no more informative fragment ions are formed.

A high mass resolution/high mass accuracy tandem mass spectrometer is also useful in metabolite characterization experiments. These instruments can determine the exact mass of a potential metabolite or of one of its fragment ions. Although several accurate mass instruments are available, the most useful for metabolite ID experiments is a quadrupole time of flight (Q-ToF) instrument. Other instruments, such as a four sector mass spectrometer or a Fourier transform mass spectrometer, are capable of achieving even higher resolution and mass accuracies; however, they are cumbersome and expensive and require a specially trained operator. The types of molecules encountered in metabolite ID experiments are typically comprised of only organic atoms and are fairly low molecular weight (<1000 Da). Ultrahigh resolution and mass accuracy are not necessary for their characterization. In addition, the Q-ToF instruments have been proven to be fairly rugged systems, capable of evaluating low concentrations of metabolites in extremely dirty biological matrices such as bile. An accurate mass instrument is particularly effective when two nominally isobaric structures are possible for a potential metabolite. These are structures that have the same unit mass, but differ in their exact mass.^[26]

There have been great advances in mass spectrometric instrumentation over the past decade. All of the instruments described above are rugged and available for routine use. While these are not the only tandem mass spectrometric systems available, when used together, they provide a powerful complement for metabolite characterization experiments. A flow chart illustrating the complementary nature and effective utilization of these various MS/MS techniques is shown in Fig. 1. The most effective use of these instruments involves setting up the front end of the systems identically. All systems should be fitted with the same LC and injection system and the mass spectrometers should be set up in parallel with a radio flow

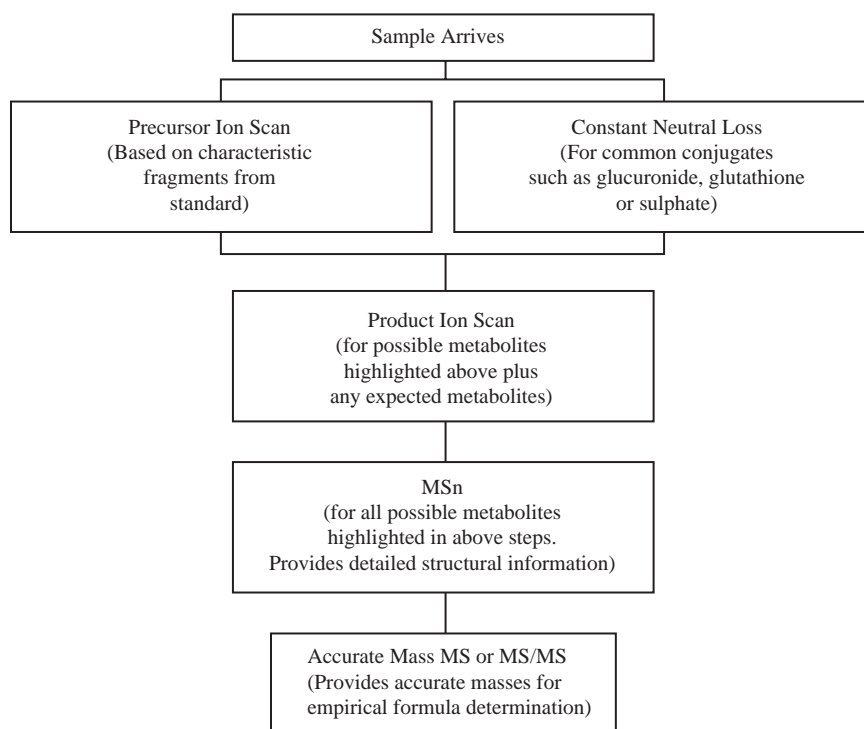

Fig. 1 Systematic approach to metabolite identification and characterization.

detector. In this manner, samples can be easily moved from one system to another for further characterization. If a sample is radioactive, the LC eluent will split after leaving the column and a portion of the sample will go into the mass spectrometer while another portion will pass into the radio flow detector. The systems can also be fitted with an on-line UV detector or other analog detection device. However, in discovery, the samples are typically extremely dirty and the metabolites are present at concentrations well below the matrix concentration, so detectors with some level of selectivity will be the most useful.

The metabolic profile of new drug entities can be evaluated in a variety of biological matrices. The advantage of *in vitro* matrices is that they provide a cleaner background, and the concentrations of metabolites can often be controlled by manipulating the incubation conditions. However, not all of the metabolic pathways are necessarily accessed through an *in vitro* system. The most comprehensive metabolic profile will be obtained from an *in vivo* system and the highest concentration of metabolites will be observed in the excreta (i.e., bile/urine/feces). Also, since these compounds are being evaluated early in discovery, these experiments often provide the first look at the metabolites of a new chemical entity. Due to this, there is a danger that routine sample cleanup methods, such as solid-phase extraction or

liquid–liquid extraction, will eliminate novel metabolites. In addition, as the new chemical entities are rarely radioactive, there is no way to trace whether critical metabolites are lost during cleanup. A more comprehensive evaluation of metabolites is obtained if the samples (bile/urine/plasma) can be analyzed directly. This again points to the need for a rugged, sensitive, and selective detection system.

SOFTWARE

It is easy to envisage how the tandem MS experiments described before could generate an enormous amount of data, leaving the daunting task of evaluating every chromatographic peak manually to the operator. However, significant advances in software technology have been made in recent years to allow a computer to critically evaluate these large datasets based on a series of preset criteria and rules. Not only does this provide a higher throughput for data evaluation, but it also leaves the operator free to design additional experiments, resulting in a more comprehensive evaluation of metabolites in a shorter time frame. As stated earlier, the most comprehensive and informative metabolite identification experiments come from the analysis of *in vivo* samples, typically bile

and urine. Bile, in particular, is an extremely dirty matrix, comprised primarily of numerous bile salts that can obscure the signals generated by potential metabolites. Since little or no sample cleanup is utilized in these samples, highly complex mass chromatograms can result. Computer algorithms now exist that will perform a detailed background subtraction on these samples, virtually eliminating contributions from the matrix. In order to perform this background subtraction, two separate experiments are performed on the LC-MS/MS system. The sample of interest is analyzed and then an injection is made of a control sample of the appropriate biological matrix. The analytical conditions are identical for each experiment, and the computer merely eliminates the peaks observed in the control biological matrix from the actual sample dataset, significantly simplifying the resulting mass chromatogram and in many cases revealing potential metabolites that were obscured by the chemical noise.

A second software feature capitalizes on the fact that many potential drug candidates contain atoms that are not naturally occurring in the body and which possess unique isotopic patterns. In particular, chlorine and bromine

atoms give unique and distinctive mass spectral signals. The computer can evaluate the sample dataset and find any chromatographic peaks that contain these characteristic isotopic patterns. An example of how these software routines can simplify a complex chromatogram is shown in Fig. 2 (reprinted with permission from American Pharmaceutical Review). This compound contained a tritium label, so the top trace (a) shows peaks corresponding to radioactive metabolites. The second trace (b) shows the total ion chromatogram (i.e., all masses from 300 to 1000 amu) with no software intervention. A background subtraction routine greatly simplifies this chromatogram in the third trace (c). Finally, this compound contains a chlorine atom, so an isotopic cluster algorithm further simplifies the resulting chromatogram in the fourth trace (d). Note how this last trace begins to resemble the radio chromatogram.

In addition, the computer can accept a list of potential or common metabolites such as hydroxylation, demethylation, or a combination of metabolic alterations. Most software packages will also accept custom alterations if the user knows of unusual metabolic processes that are specific

Fig. 2 Various software cleanup methods in the evaluation of metabolites of Compound X in rat bile. (From Ref. 26.)

for a given structural series of compounds. The software programs can calculate these masses, given only the mass of the parent drug, and search the resulting mass chromatograms for the presence of these metabolites. Furthermore, given a set of evaluation criteria, the computer can assess the integrity of the observed peaks to determine whether they represent real entities. Acceptance criteria can be dictated by the user and consist of factors such as how high the analytical signal is above the background noise and the width of the peak. These techniques are particularly powerful when used in conjunction with accurate mass data, as the masses of potential metabolites can be precisely determined and distinguished from other contaminants that may have the same nominal mass, but differ in their exact mass.

Most of the commercial software packages currently available offer a browser screen that allows the operator to view the peaks the computer picks out as potential metabolites and lets the operator have final say in whether these peaks should be evaluated further as potential metabolites. The software programs can then automatically set up additional MS/MS experiments for further characterization of these metabolites, significantly eliminating the amount of user intervention necessary. These experiments can be set up to run automatically overnight, leaving the results available for user evaluation in the morning. This type of data “mining” provides a rapid and efficient way of evaluating the tremendous amount of data generated in a mass chromatogram, significantly reducing the amount of manual data interpretation required by the user and increasing the throughput of metabolite identification experiments. A flow diagram of the metabolite software decision process is shown in Fig. 3 (reprinted with permission from American Pharmaceutical Review).

CONCLUSIONS AND FUTURE TRENDS

The contributions of metabolite identification studies to early drug discovery are often significant. It is of critical importance to a discovery program to know what metabolites are formed as this can drive the structural chemistry effort toward more effective drugs. It also provides an opportunity to obtain an early look at human metabolism from *in vitro* systems to make sure that there are no metabolites produced by human enzymes that are not adequately produced by other animal species. This can result in a higher success rate of drug candidates that make it into the clinical phase. However, only in recent years, with the considerable hardware and software advances in the use of LC-MS/MS technology, it has been realistic to implement these types of studies into the high throughput

environment of drug discovery. It is also important to redefine the goals of a metabolite identification experiment in the discovery environment. Many compounds in a structural series need to be evaluated in a fairly short time frame and often it is more important to point to metabolically labile portions of the molecule quickly rather than to spend months elucidating the exact stereospecific structure of a single metabolite. Furthermore, sample volumes are small and rarely radiolabeled. LC-MS/MS is a powerful analytical technique and can be used effectively to evaluate samples under these conditions. The mass spectrometer is a selective and sensitive detector, and is able to detect and characterize low levels of metabolites out of extremely complex biological matrices. The precursor and constant neutral loss scanning capabilities of an MS/MS instrument provide the means of searching through a complex mixture to find any entities that have structural similarities to the parent drug compound, and often very little prior information is necessary to make use of these experiments. Data from product ion scan experiments provide further structural characterization of potential metabolites and use of MSⁿ and accurate mass capabilities can narrow the site of modification even further and provide insight into the empirical formula of metabolites. The integration of these complementary MS/MS techniques provides an efficient and comprehensive approach to metabolite characterization.

The recent development of “smart” software programs allows the computer to quickly and critically evaluate large, complex datasets. This significantly reduces the amount of manual data interpretation required by the user and large datasets can be evaluated more rapidly. However, data interpretation is still crucial and continues to be the bottleneck to even higher throughput studies. To address this, the software programs are continuing to evolve in response to user needs. Data-dependent scanning capabilities are being developed to make the most use out of a single injection. Once the computer detects a potential metabolite in an LC run, it can automatically switch to a tandem mode to provide structural information on that metabolite “on the fly.” This type of experiment shows a great deal of potential; however, it is still problematic for extremely dirty samples such as bile.

Future software programs will also be able to utilize the input from other external analog detectors such as radio flow or UV detectors to further enhance the resulting dataset. In addition, there are software programs that are capable of interpreting MS/MS spectra and provide suggestions for the structures of the observed fragment ions. Mathematical programs such as CODA can further distinguish what is a real chemical signal and what is random noise in a dataset and correlation analysis can

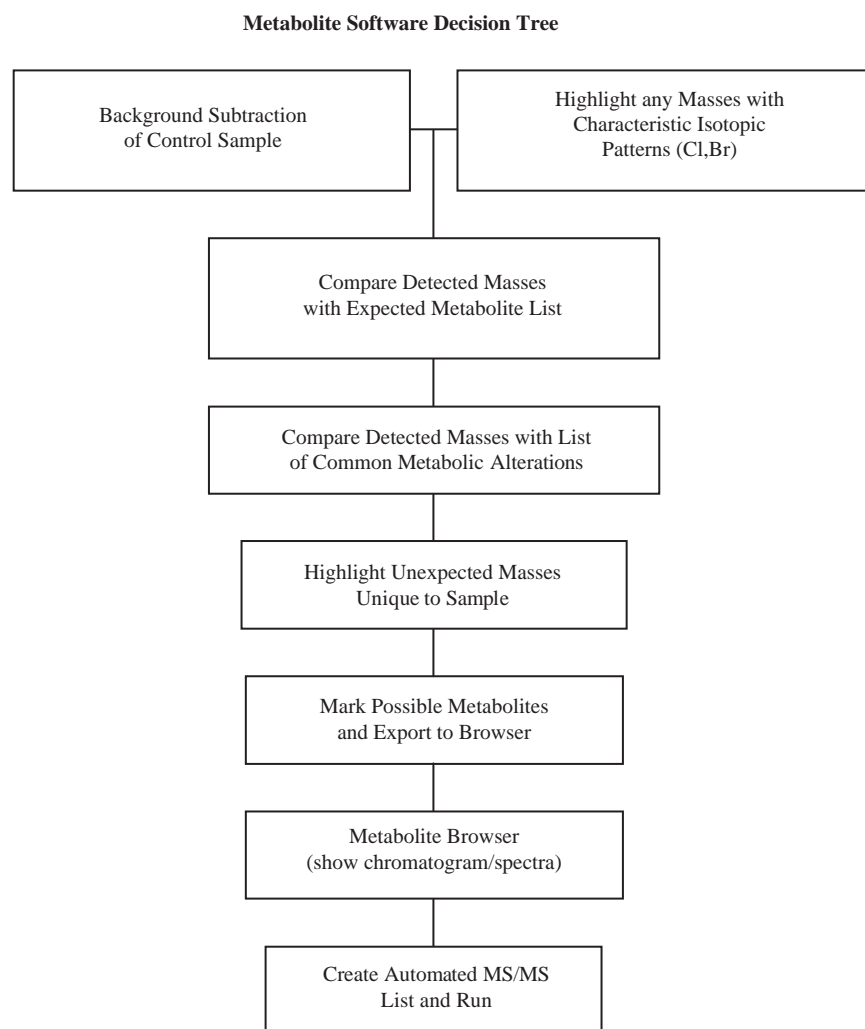

Fig. 3 Metabolite software decision tree. (From Ref. 26.)

evaluate complex matrices, pick out potential metabolites, and determine the degree of similarity between these observed compounds and the parent drug compound.^[27] Efforts are also being made to utilize the Internet and establish links to existing metabolite databases. Once a metabolite is discovered experimentally, the software will search the database to determine whether that type of metabolic alteration has been observed before and under what circumstances.

Implementation of metabolite identification studies into drug discovery is still very much an evolving process. Significant technological advances have been made over recent years and scientists are continuing to adapt and develop existing techniques to the rigorous demands of a discovery environment. While metabolite ID is by no means “high throughput,” experiments exist that can give timely and valuable information back to the discovery

project teams, driving the evolution of lead compounds and answering critical metabolic questions that will ultimately save the pharmaceutical company time, money, and resources in the future. Based on the value of these studies, the contributions from metabolite ID studies within drug discovery are only expected to increase in the future.

Melt Processes for Oral Solid Dosage Forms

Paul W.S. Heng

Tin Wui Wong

National University of Singapore, Singapore

INTRODUCTION

The design of pharmaceutical solid dosage form using meltable materials has become increasingly popular as alternative special processes to avoid aqueous or organic solvents. Its application has extended to the processing of solid dispersion, agglomerate, microsphere, and nanosphere for the administration of drugs via oral and parenteral routes.

The processing and drug release properties can be partly or wholly affected by the physicochemical characteristics of meltable materials. The judicious choice of the meltable material to be used has considerable influences on the property and quality of the resulting solid dosage form.

OVERVIEW

The manufacture of solid dosage forms using meltable materials has many advantages when compared with the conventional wet techniques. The avoidance of using aqueous solvent made the melt technique suitable for formulating moisture-sensitive drugs. The use of flammable organic solvents for processing effervescent and hygroscopic materials can be avoided, thus reducing the needed cost for flame-proof facilities and solvent-recovery equipment. Materials processed by the melt technique do not require solvent removal or a drying phase. The total processing time is shorter. By an appropriate selection of meltable materials, both immediate- and prolonged-release solid dosage forms can be prepared. Hence the release rate of a drug can be controlled by varying the composition of the meltable materials.

The most obvious disadvantage of the melt technique is that the process cannot be applied to heat-sensitive materials owing to the elevated temperatures involved. Nonetheless, *Lactobacillus acidophilus* bacteria, formulated by continuous melt technology, were found to have a higher survival rate than those prepared by conventional wet techniques, although the molten mass had a temperature of more than 100°C.^[1] Moisture often aggravates the thermolability of pharmaceutical materials. The absence of moisture minimizes the heat-related degradation.

Thus it can be concluded that the melt technique for processing heat-sensitive materials warrants further studies.

The melt processes require at least a meltable material in the manufacture of the solid dosage form. This article intends to address the influence of meltable materials on the processes of melt pelletization, melt granulation, and tumbling melt granulation. Approaches to meet the processing attributes of the meltable materials for these melt agglomeration processes, via spray congealing, are discussed.

GENERAL INFORMATION

The processors for both melt and wet techniques share similar features.^[2-7] Material processing by the melt technique essentially requires the heating jacket, thermal insulator, high-speed/high-shear agitation, and/or atomization equipment. Melt processing is accompanied by either a size enlargement or a reduction of the particles. Materials employed may be of single or multiple meltable components, as well as a mixture of meltable and non-meltable components. In the latter mixture, the weight proportion of nonmeltable component may vary from 10% to 90% depending on the design of the solid dosage form. The end products are usually granules or pellets produced by a one-step, one-run process.

In design and development of a formulation by melt processes, multiple-unit solid dosage form is popular with manufacturers as it allows a high degree of flexibility in modifying the dosage regimen. Multiple-unit solid dosage form can be designed with different proportions to meet the desired dose strength without altering the drug load in each entity by processing and/or formulation changes. Entities of different drugs that are not chemically compatible or containing the same drug but with different release rates may be blended in an appropriate ratio. Multiple-unit solid dosage form may effect drug release at the same site or at different sites along the route of administration and is less susceptible to dose dumping.

By the size enlargement processes, melt agglomeration may be employed to produce multiple-unit solid dosage form. The melt agglomerates are called granules when the end product has a wide size distribution spanning between 0.1 and 2 mm. The agglomerates are termed pellets if the

end product is spherical in shape and has a narrow size distribution of 0.5–2 mm. Melt pellets are often dispensed as a multiparticulate dosage form, whereas melt granules may be encapsulated or further subjected to tableting processes. The formative and growth processes of melt agglomerates are critically dependent on the physico-chemical properties of the meltable materials, which may be modified by spray congealing. Unlike melt agglomeration, which requires both meltable and nonmeltable components, spray congealing is able to process meltable materials with or without the nonmeltable component.

Melt Pelletization/Melt Granulation

Melt agglomeration is a process by which the solid fine particles are bound together into agglomerates, by agitation, kneading, and layering, in the presence of a molten binding liquid. Dry agglomerates are obtained as the molten binding liquid solidifies by cooling. Typical examples of melt agglomeration processes are melt pelletization and melt granulation. During the agglomeration process, a gradual change in the size and shape of the agglomerates would take place. It is usually not possible to clearly distinguish between granulation and pelletization. Thus granulation is considered a pelletization process when highly spherical agglomerates of narrow size distribution are produced. Conversely, an unsuccessful pelletization process may be classified as granulation.

The equipment for melt agglomeration include rotating drums or pans, fluid-bed granulators, low-shear mixers such as Z-blade and planetary mixers, and high-shear mixers. Presently, the more popular agglomeration equipment for industrial-scale production are high-shear mixers and fluid-bed granulators. In both methods, a gradual buildup of agglomerates occurs during the process. The marked difference between the methods is the absence of shearing forces in the fluid-bed process, whereas very high shearing forces are generated in high-shear mixing.

During a melt agglomeration process, the meltable binder may be added as molten liquid, or as dry powder or flakes. In the latter, the binder may be heated by hot air or by a heating jacket to above the melting point of the binder. Alternatively, the melt agglomeration process exploits an extremely high shear input, of a high-shear mixer, where the heat of friction alone raises the temperature of the binder and effects melting. Polyethylene glycols, fatty acids, fatty alcohols, waxes, and glycerides are some examples of meltable binders. Polyethylene glycols are commonly used as meltable binders when aqueous soluble binders are needed, while fatty acids, fatty alcohols, waxes, and glycerides are desirable meltable binders for products to be insoluble in the aqueous medium. Typically, the melting points of meltable binders range from 50 to 80°C. A lower-melting-point binder

risks situations where melting or softening of the binder occurs during handling and storage of the agglomerates. Higher-melting-point binders require high melting temperatures and can contribute to instability problems especially for heat-labile materials.

In assessing the influence of meltable materials on the formative and growth processes of melt agglomerates, it is imperative to have a thorough understanding of the melt agglomeration process. The mechanism of melt agglomeration is similar to that of wet agglomeration. An agglomerate growth is affected by the saturation state of the liquid in the agglomerate pore structure. However, the formation and growth of melt agglomerates are not complicated by binding liquid losses via evaporation during the agglomeration process. Agglomerative mechanisms can be subdivided as nucleation, coalescence, and layering (Fig. 1). These mechanisms are believed to constitute a complex set of elementary events that directly or indirectly influence the formative and growth processes of agglomerates. Nucleation is predominant with fine particles. It involves primary solid particles being bound together, on addition of a binding liquid, to form a three-phase air–solid–liquid loose cluster, which eventually lead to the formation of a primary nuclei. The particles are held by liquid bridges in a pendular state (Fig. 2). The formation of larger agglomerates followed successful random internuclei collisions by a process known as coalescence. Coalescence involves nuclei that have residual surface liquid to promote successful fusion of nuclei. The surface liquid imparts plasticity to the nuclei and is essential for enabling the deformation of nuclei surfaces for coalescence as well as promoting the rounding of agglomerates. Excess surface liquid may be increased by adding a binding liquid or by densification as a result of mechanical forces where liquid is squeezed out from the interior to the surfaces of agglomerates (Fig. 2). During coalescence, the liquid-bridging state of the nuclei changes from pendular through funicular to capillary state. Fine particles may be generated by random collisions during the size-enlargement processes. These

Fig. 1 Mechanisms of agglomeration.

Fig. 2 Liquid-bridging state of agglomerates undergoing (a) binding liquid addition and (b) densification.

particles could be layered onto the preformed nuclei. Alternatively, fine particles may be supplemented by addition, either as a dry powder or molten mass, onto the preformed nuclei that are many orders of magnitude larger than the added material, to effect size enlargement by a layering process.

Two modes of melt agglomeration based on the elementary mechanisms have been proposed—distribution and immersion.^[8] In agglomeration by the distribution mode, a distribution of molten binding liquid on the surfaces of primary particles will occur, and agglomerates are formed via coalescence between the wetted nuclei (Fig. 3). In agglomeration by the immersion mode, nuclei are formed by immersion of the primary particles into the surface of a droplet of molten binding liquid (Fig. 3). The distribution of molten binding liquid to surfaces of nuclei has to be effected by densification prior to coalescence between the nuclei. Depending on the

relative size between the solid particles and the molten binding liquid droplets, the distribution will be a dominant mode when the molten binding liquid droplets are smaller than the solid particles or of a similar size. On the other hand, the immersion mode will dominate when the molten binding liquid droplets are larger than the solid particles. The distribution mode is promoted by a low molten binding liquid viscosity. In the case of immersion, it is more favorable for molten binding liquid of high viscosity, which could resist breakup by dispersive forces.

Melt agglomeration by the immersion mode produced slower initial agglomerate growth rate than that by the distribution method. At the initial phase of melt agglomeration, the surface plasticity of agglomerates bound by large molten binding liquid droplets of a high viscosity is lower. This translates to a reduced growth propensity of melt agglomerates by coalescence. However, with a greater extent of densification by prolonging the period

Fig. 3 Modes of melt agglomeration: (a) Distribution and (b) immersion.

of processing or by using high impeller speed, the agglomerates attain a comparable surface wetness and deformability. As the surfaces of these agglomerates are wetted by a molten binding liquid of higher viscous or tack forces, the growth propensity of agglomerates becomes increasingly greater and, at times, can be uncontrollable. Meltable binders are available as flakes, powders, or fine powders. Practically, the melt agglomeration process is less dependent on the particle size of a meltable binder except when a very high viscosity binder is used.^[8–10]

During melt agglomeration, the liquid saturation state has to be near the droplet state for highly viscous molten binding liquid to be sufficiently deformable for agglomerate growth by coalescence. There is a high risk of overwetting and uncontrollable agglomerate growth. A higher impeller speed may be applied to prevent an uncontrollable agglomerate growth by ensuring continuous comminution.^[11] Unlike the wet agglomeration process, the melt agglomeration process cannot be controlled through the removal of excess surface liquid by evaporation. However, evaporation of water of crystallization from the solid hydrate during a melt agglomeration process could render the growth process of agglomerates more controllable, probably by reducing the surface wetness through absorption of binding liquid into small pores formed in the agglomerate surfaces as a result of the loss of water of crystallization.^[12]

It is envisaged that melt agglomeration employing highly viscous molten binding liquid can also be controlled by using an impeller blade of appropriate geometry, which generates high relative swept volume or shear input,^[13] large solid particles as nonmeltable components that form agglomerates of low mechanical strength susceptible to comminution^[14] as well as keeping the off-bottom clearance, which critically affects the flow dynamics of the processing materials within a narrow range.^[15] Indirectly, melt agglomeration may be subjected to real-time monitoring of the process energy consumption, which is an indication of the work load for agglomeration.^[16,17]

Table 1 presents a list of meltable binders previously employed in melt agglomeration. These meltable binders vary in their melting range, hydrophilicity–hydrophobicity, and molecular size. The molten binding liquid viscosity has largely been identified as the core characteristic of meltable binders that has a strong bearing on the melt agglomeration process. In hydrophobic meltable binders, such as stearic acid, which has very low viscosity values below 50 mPa sec at the melting temperatures ranging from 70 to 90°C, the melt agglomeration process is more markedly dependent on the balance between the coalescence and the breakage of agglomerates.^[18] By using meltable binders with very low viscosities, it is

Table 1 Types of meltable binders in the melt agglomeration process

	Typical melting range (°C)
<i>Hydrophilic meltable binder</i>	
Gelucire 50/13	35–44
Poloxamer 188	~ 50.9
Polyethylene glycol	
2000	42–53
3000	48–63
6000	49–63
8000	54–63
10000	57–64
20000	53–66
Stearate 6000 WL1644	46–58
<i>Hydrophobic meltable binder</i>	
Beeswax	56–60
Carnauba wax	75–83
Cetyl palmitate	47–50
Glyceryl behenate	67–75
Glyceryl monostearate	47–63
Glyceryl palmitostearate	48–57
Glyceryl stearate	54–63
Hydrogenated castor oil	62–86
Microcrystalline wax	58–72
Paraffin wax	47–65
Stearic acid	46–69
Stearic alcohol	56–60

highly probable that crushing and layering are the dominant growth mechanisms occurring concurrently with coalescence. The melt agglomerates are more susceptible to breakage as a result of the low viscous strength. The formed agglomerates, compared to that prepared using higher-viscosity meltable binders, are usually smaller with wider size distribution, more porous, and less spherical in shape.

Tumbling Melt Granulation

A newer melt agglomeration technique, i.e., tumbling melt granulation, for preparing spherical beads has been reported.^[19–21] A powdered mixture of meltable and nonmeltable materials is fed onto the seeds in a fluid-bed granulator (Fig. 4). The mixture adheres onto the seeds with the binding forces of a melting solid to form the spherical beads. In preparing the spherical beads, both viscosity and particle size of the meltable materials should be kept at an optimum value. The particle size of a meltable material should be 1/6 or lower than the diameter of the seeds. High-viscosity meltable materials should not be employed to avoid agglomeration of seeds and producing beads of low sphericity.

Fig. 4 Process of tumbling melt granulation.

Both particle size and viscosity of the meltable materials play a significant role in the melt agglomeration process. The control of the melt agglomeration process is best initiated by using meltable materials of controlled properties. For the melt pelletization and melt granulation processes, it is desirable that meltable materials have a high viscosity to improve the mechanical strength of the agglomerates, but a reduced particle size to prevent uncontrollable agglomerate growth. In tumbling melt granulation, small meltable particles with sufficient viscous binding forces are obligatory for the production of spherical beads.

Spray Congealing

Spray congealing is a melt technique of high versatility. In addition to manufacture multiparticulate delivery system,^[22,23] it can be applied to process the raw meltable materials into particles of defined size and viscosity values for the melt agglomeration process. Processing of meltable materials by spray congealing involves spraying a hot melt of wax, fatty acid, or glyceride into an air chamber below the melting point of the meltable materials or at cryogenic temperature. Spray-congealed particles (10–3000 μm in diameter) are obtained upon cooling. The congealed particles are strong and nonporous as there is an absence of solvent evaporation. Ideally, the meltable materials should have defined melting points or narrow melting ranges. Viscosity modifier, either meltable or non-meltable at the processing temperature, may be incorporated into the meltable matrix to change the consistency of the molten droplets.

CONCLUSION

The viscosity and particle size of a meltable material critically affect the formative process of the melt agglomerates. Thus their size, size distribution, shape, and

mechanical strength are also affected. This leads to an increasing interest to design meltable materials of required properties suitable for special melt processes. In the design and production of meltable materials with desired particle size and viscosity grade, spray congealing is a potential technique to be employed and developed for industrial application. Spray congealing technique is expected to gain widespread use with recent growing interest in melt pellets as controlled-release solid dosage form.

MUCOADHESIVE HYDROGELS IN DRUG DELIVERY

Hans E. Junginger

Maya Thanou

J. Coos Verhoef

Leiden/Amsterdam Center for Drug Research, Leiden University, The Netherlands

INTRODUCTION

This article focuses on defining the principles of bioadhesive delivery systems based on hydrogels to biological surfaces that are covered by mucus. An overview of the last decade's discoveries on mucoadhesion and applications of mucoadhesive hydrogels as drug carriers is given. Techniques that are frequently used to study the adhesion forces and physicochemical interactions between hydrogel, mucus, and the underlying mucosa are reviewed. Typical examples of applications of mucoadhesive hydrogels to mucosal routes of delivery are given. Finally, the perspectives of the application of these polymers in drug delivery are discussed.

Noninvasive drug delivery may require the administration of the drug delivery system (DDS) at an epithelium as a suitable site of absorption of the active compound. Such regions are usually called mucosae. In the human body several mucosal sites can be identified, the one mostly used for administration and absorption of therapeutics being the gastrointestinal route. In order to increase the residence time at these absorption sites, a so-called mucoadhesive delivery system has to be used. Generally, these systems consist of one or more types of hydrogels.

By definition, mucoadhesive hydrogels are a class of polymeric biomaterials that exhibit the basic characteristic of a hydrogel to swell by absorbing water and interacting by means of adhesion with the mucus that covers epithelia.

Bioadhesion has been defined as the attachment of synthetic or biological macromolecules to a biological tissue (1). The term mucoadhesion refers to the special case of bioadhesion where the biological tissue is an epithelium covered by mucus. Mucus is a thin blanket covering all epithelia that are in contact with the external environment in the gastrointestinal, respiratory, and urogenital tracts. The function of mucus is mainly the protection and lubrication of the underlying epithelium, but it may have additional functions dependent on the type of the covered epithelia. In each case of these mucosal routes, mucus characteristics (i.e., thickness) and functions are different. By this definition, the mucosal routes for drug delivery are:

- Buccal/oral route
- Nasal route
- Ocular route
- Vaginal route
- Gastrointestinal route

The concept of mucoadhesion in drug delivery was introduced in the field of controlled-release drug delivery systems in the early 1980s (2, 3). Thereafter, several researchers have focused on the investigations of the interfacial phenomena of mucoadhesive hydrogels (and of other type mucoadhesive compounds) with the mucus. Several techniques of studying these interactions were evaluated both in vitro and in vivo. These techniques have been recently reviewed by Harding et al. (4) and are given in Table 1.

A mucoadhesive hydrogel used as a drug delivery system should

1. Be loaded substantially by the active compound;
2. Not interact physicochemically with the active compound or create a hostile artificial environment that would lead to inactivation and degradation of the active compound;
3. Swell in the aqueous biological environment of the delivery-absorption site;
4. Interact with mucus or its components for adequate adhesion;
5. Allow, when swelled, controlled release of the active compound;
6. Be biocompatible (biomaterial) with the underlying epithelia by means of complete absence of cytotoxicity, ciliotoxicity, or other type of irreversible alterations of the cell membrane components;
7. Have the appropriate molecular size and conformation in order to escape systemic absorption from the administration site; and
8. Be excreted unaltered or biologically degraded to inactive, nontoxic oligomers/monomers that will be further subject of physical clearance.

Additionally, a mucoadhesive delivery system designed for controlled release of active compounds should be localized at specific sites of administration and absorption,

Table 1 Methods of studying mucoadhesion

Method	Comment
Direct assays	
Tensiometry	Force required to dislodge two surfaces, one coated with mucus, the other solid dosage form consisting of mucoadhesive hydrogel
Flow through	Flow rate dV/dt required to dislodge two surfaces; useful for microparticulate dosage forms
Colloidal gold staining	Measures the “adhesion number”
In vivo techniques	Endoscopy, gamma scintigraphy
Molecular mucin-based assays	
Viscometry and rheology	Intrinsic viscosity $[\eta]$ can be related to complex size via MHKS, ^a α coefficient
Dynamic light scattering	Diffusion coefficient, D , can be related to complex size via MHKS c. coefficient
Turbidity, light scattering	SEC MALLS ^b particularly useful for determining MW of mucin, turbidity, semiquantitative indicator
Analytical ultracentrifugation	Change in MW (sedimentation equilibrium), sedimentation coefficient ratio of complex to mucin
Surface plasmon resonance imaging methods	Needs mobile and immobile phase, atomic force microscopy (conventional and gold labeled), scanning tunneling microscopy

^aMark-Houwink-Kuhn-Sakurada.^bSize exclusion chromatography multiangle laser light scattering.

(Adapted from Ref. 4.)

and should prolong the residence time of the active compound at the site of administration to permit, if possible for one daily dosing.

The mucoadhesive delivery system, designed for the administration of macromolecular therapeutics like peptide or protein drugs, should have permeation-enhancing properties by means of alteration of the permeability properties of the underlying epithelium, and should protect the peptide drug from degradation by inhibiting the proteolytic enzymes usually present at the site of administration or by stabilizing the intrinsic environment of the delivery system by sustaining the suitable pH.

Solid dosage forms based on mucoadhesive polymers are used mainly for buccal delivery of drugs, whereas micro- or nanoparticulate formulations are preferred for the delivery of therapeutics in the nasal and intestinal tract (5).

During the last decade research was particularly focused on the delivery of mucoadhesive dosage forms in the gastrointestinal tract, which is the most favorable route of delivery with regard to patient compliance and ease of application. For this reason microparticulate formulations, consisting of mucoadhesive hydrogels, were designed and evaluated by different techniques (6, 7). However, solid dosage forms are more suitable for smaller cavities in the human body, like the oral cavity, either for systemic absorption of compounds or for local treatment of inflammatory diseases. In this case, monolithic devices

(tablets) made from mucoadhesive hydrogels were evaluated (8). Ocular and vaginal applications (for local or systemic absorption) of mucoadhesive hydrogels were also investigated.

The mucoadhesive properties of several classes of hydrogels have been identified, and two types of polymers have attracted special attention. Polyacrylates and their cross-linked modifications represent the anionic type, chitosan and its derivatives the cationic group. In addition, both types of polymers show a number of interesting characteristics beneficial for the administration of a wide range of therapeutics.

Specific type of mucoadhesive compounds, like lectins, have been evaluated to solve the difficulties presented by conventional mucoadhesive hydrogel systems, for instance in the gastrointestinal route. Since these compounds do not belong to the class of hydrogels, they are not extensively discussed here.

MUCUS

In higher organisms epithelia are covered by a protective gel layer defined as mucus. By weight, mucus consists mainly of water (95–99.5%) in which the mucous glycoprotein mucin (0.5–5%) is dispersed. Mucins are

the major components responsible for the gel-like structure of the mucus. They possess a linear protein heavily glycosylated by oligosaccharide side chains. This protein core consists of a single polypeptide chain. One in every three residues is L-serine or L-threonine, in which the O-3 atoms provide the sites for glycosidic linkage. A mucus glycoprotein is composed typically of about 80% of carbohydrates, which for humans are restricted to five monosaccharides:

- L-Fucose
- *N*-Acetylglucosamine
- D-Galactose
- *N*-Acetylgalactosamine
- Sialic acid

The sialic acid residues are usually in a terminal position on the carbohydrate chain whereas the ester sulfate residues are in a more internal position; both contribute to give the molecule a net negative charge. The molecular weights of mucus glycoproteins range from 0.5 to 16×10^6 Da (4).

Mucins can be divided into two classes, membrane bound and secretory forms. Membrane-bound mucins are attached to cell surfaces and may affect immune responses or inflammation. It has been suggested that the high expression of cell-surface mucins, such as sialomucin MUC1, may result in cell–cell and cell–matrix interactions (10). Secretory mucins emanate from mucosal absorptive cells and specialized goblet cells. They constitute the major component of mucous gels in the gastrointestinal, ocular, respiratory, and urogenital epithelia. This type of mucus gel layer is functioning mainly as a physical barrier and lubricant. Important constituents in the mucus include growth factors and trefoil peptides, both secreted by the specialized cells located next to ulcerated mucosal tissue. This appears to be an adaptive phenomenon, important in maintaining the barrier function of the mucosal tissue, enhancing cell migration, and healing after injury. Other substances present in mucus include secretory immunoglobulin A (IgA), lysozyme, lactoferrin, α_1 -Antitrypsin, salts, and *N*-Glycosylated glycoproteins (10).

At present, nine different human epithelial mucin genes have been identified, each of which contains distinct sequences repeated in tandem that encode (apo)mucin core polypeptides (MUC) (10).

Leung and Robinson (11) defined four characteristics of the mucus layer related to mucoadhesion:

1. Mucus is a network of linear, flexible, and random-coil macromolecules.
2. Mucin is negatively charged due to sialic acid and sulfate residues.

3. Mucus is a cross-linked network connected by disulfide bonds between mucin molecules.
4. Mucin is heavily hydrated.

Several techniques have been used to estimate the rate of mucus secretion, but their accuracy seems to be doubtful. Nevertheless, it has been concluded that a slow baseline secretion of mucus is maintained by exocytosis from goblet cells in the gastrointestinal tract, which appears to be under cholinergic control (12). Rubinstein and Tirosh used carbachol (cholinergic agonist) at different doses to increase the mucus thickness in different parts of the gastrointestinal tract (13).

Attempts were also made to estimate the rate of turnover of the mucus gel. Lehr et al. (14) measured the amount of mucus produced per time unit, using an in situ perfused intestinal loop model in the rat. They found that this turnover time varies between 0.8 and 4.5 h.

MECHANISM AND THEORIES OF MUCOADHESION

The mechanistic processes involved in mucoadhesion between hydrogels and mucosa can be described in three steps:

1. Wetting and swelling of the polymer to allow for intimate contact with the biological tissue.
2. Interpenetration of the bioadhesive polymer chains and entanglement of polymer and mucin chains, and
3. Formation of weak chemical bonds between entangled chains (Fig. 1).

Several theories have been proposed to explain the biomucoadhesive phenomena (1, 15–17).

The electronic theory is based on the assumption that the mucoadhesive hydrogel and the target biological tissue have different electronic structures. When two materials come into contact with each other, electron transfer occurs, causing the formation of a double layer of electrical charge at the bioadhesive–biological interface. The bioadhesive force is believed to be due to attractive forces across this electrical double layer.

The adsorption theory states that the bioadhesive bond formed between an adhesive substrate and tissue or mucosae is due to van der Waals interactions, hydrogen bonds, and related forces. Alternatively, when mucus or saliva are interacting with a solid dosage form, the molecules of the liquid are adsorbed on the solid surface. This is an exothermic process. The free energy of adsorption is given by

$$\Delta G_{AD} = \Delta H_{AD} - T \Delta S_{AD} \quad (1)$$

Fig. 1 Three stages in the interaction between a mucoadhesive polymer and mucin glycoprotein according to the interpenetration theory.

where ΔH_{AD} and ΔS_{AD} are the enthalpy and entropy changes, respectively. When adsorption takes place spontaneously, ΔG_{AD} is negative.

The contact angle θ of a liquid on a solid is the reflection of its wetting power. If $\theta = 0$, the liquid spreads freely on the solid surface and wets it. The relationship between the contact angle of a liquid on a solid and the surface tensions in the presence of saturated vapor of the liquid is given by the Young equation

$$\gamma_{sv} = \gamma_{sl} + \gamma_{lv} \cos \theta \quad (2)$$

where γ_{sv} is the solid/vapor surface tension, γ_{sl} the solid/liquid surface tension, and γ_{lv} the liquid/vapor surface tension.

Another way to relate the interfacial tension γ_{sl} to the individual surface tensions of a liquid and solid is given by the Good equation.

$$\gamma_{sl} = \gamma_{sv} + \gamma_{lv} - 2\phi(\gamma_{sv}\gamma_{lv})^{1/2} \quad (3)$$

Eq. 3 represents the reduction in interfacial tension resulting from molecular attraction between liquid and solid. The term ϕ is defined by

$$\phi = W_a/(W_{cl}W_{cs})^{1/2} \quad (4)$$

where W_{cl} and W_{cs} are the work of cohesion of the liquid and the solid, respectively, and W_a is the work of adhesion.

The diffusion theory states that interpenetration and entanglement of polymer chains are additionally responsible for bioadhesion. The intimate contact of the two substrates is essential for diffusion to occur; that is, the

driving force for the interdiffusion is the concentration gradient across the interface. The penetration of polymer chains into the mucus network, and vice versa, is dependent on concentration gradients and diffusion coefficients. It is believed that for an effective adhesion bond the interpenetration of the polymer chain should be in the range of 0.2–0.5 μm . It is possible to estimate the penetration depth (l) by

$$l = (tD_b)^{1/2} \quad (5)$$

where t is the time of contact and D_b is the diffusion coefficient of the bioadhesive material in the mucus.

The fracture theory is the most widely applied theory in studying mucoadhesion mechanisms. It accounts for the forces required to separate two surfaces after adhesion. The maximum tensile stress (σ) produced during detachment can be determined by Eq. 6 by dividing the maximum force of detachment F_m by the total surface area (A_0) involved in the adhesive interaction:

$$\sigma = F_m/A_0 \quad (6)$$

According to Duchêne and Ponchel (17), when tensiometry is used to measure the maximum detachment force as a function of the displacement of the upper support (function of the joint elongation), the work of bioadhesion can be defined as

$$W_b = F \times l \quad (7)$$

Additionally, the fracture energy for a zero extension rate can be defined as the bioadhesion work to the initial surface between the bioadhesive material (in the form of a tablet or disk) and the biological support of a surface A_0 , which allows for calculation of the fracture energy (ϵ) using

$$\epsilon = W_b/A_0 \quad (8)$$

Thermodynamically, the fracture energy is the sum of the reversible work (W_r , representing the reversible molecular interactions at the interface) and irreversible work (W_i representing the irreversible deformation of the interfacial joint); both W_r and W_i are expressed per unit area of the fracture energy by.

$$\epsilon = W_r + W_i \quad (9)$$

When a low extension rate is used for the measurements (for instance 1 mm/min), W_i can be considered as negligible and the fracture energy for zero extension rate (ϵ_0) is then equal to the reversible work of bioadhesion W_r , as shown by

$$\epsilon_0 = W_r = W_b/A_0 \quad (10)$$

The fracture theory does not take into account biological phenomena such as stress caused, for example, by movement of the tissue.

THE STUDY OF MUCOADHESION OF HYDROGELS

During the last decade several methods to study mucoadhesion phenomena or mucoadhesive properties of hydrogels were used (Table 1). Tensiometry has already been reported as a suitable method during late 1980s and is still the most frequently used technique to study mucoadhesiveness of hydrogels. Peppas and coworkers developed a tensile technique for measurements of the bioadhesive strength of tablets containing polyacrylic acid to bovine mucosae (16, 18). A tensiometry setup for the investigation of solid devices is shown in Fig. 2. The system is better mimicking the *in vivo* conditions when the experiment is performed in an aqueous environment and the mucosa of interest is originating from freshly prepared biological tissue. It has been suggested that this system is most suitable for buccal or vaginal application, where biological liquid is controllable. Tensiometry has been shown to be very useful in comparing the mucoadhesive properties of different hydrogels (19).

Mikos and Peppas (20) described the flow channel to measure the bioadhesion of polymer microparticles on mucin gels. Later Lehr et al. (21) used an *in situ* loop model in the rat for the investigation of mucoadhesive microspheres (Fig. 3). They concluded that this approach allowed the study of the transit of particles. Another technique to study the mucoadhesive properties of microspheres is the electrobalance method, as described by Chickering et al. (22, 23). Environmental conditions

like temperature and pH can be easily controlled and several parameters can be obtained from one single experiment. The authors suggested that mucoadhesion in the bioerodible materials used to conduct the studies is not attributable to chain entanglement but to hydrogen bonding between hydrophilic functional groups (COOH) and mucus glycoproteins.

Colloidal gold staining has been introduced by Park (24) for studying the "adhesion number." The polymer in a form of strips is incubated with colloidal gold–mucin conjugates, and after a rinsing procedure the absorbance of strips is measured. Colloidal gold staining has also been used to investigate mucin–chitosan interactions (25).

Rheology measurements were used by Mortazavi et al. (26, 27) to investigate mucus–Carbopol 934P interactions at different pH values and the role of water movement in mucoadhesion. Similar rheological techniques were applied for studying four different types of polymers, and it was concluded that molecular interpenetration is an important factor in mucoadhesion by strengthening the mucus in the mucoadhesive–mucosal interface (28). Rheological methods were used to investigate the interpenetration between ion-sensitive polymers (Carbopol and deacetylated gellan gum, Gerlite) with two commercially available mucins: submaxillary gland mucin and porcine gastric mucin (29). It was suggested that the increase in the elastic modulus of a polymer–mucin mixture (compared to the elastic modulus of polymer alone) indicates a positive interaction caused by mucoadhesion. However, the concentration of the polymer, the type of the mucin used, and the quantity of ions present appeared to have a strong influence on the interactions between mucins and ion-sensitive polymers, indicating that the explanation of mucoadhesion by means of interpenetration should be applied only to interpret special cases of mucoadhesion between polymers and mucins.

Rossi et al. (30) evaluated rheologically mucins of different origin with polyacrylic acid and sodium carboxymethyl cellulose. The same group also reported a novel rheological approach based on a stationary viscoelastic test (creep test) to describe the interaction between mucoadhesive polymers and mucins (31, 32). Jabbari et al. (33) used attenuated total-reflection infrared spectroscopy to investigate the chain interpenetration of polyacrylic acid in the mucin interface.

Other techniques used for studying molecular interactions between polymers and mucus include ultracentrifugation, surface plasmon resonance, and electromagnetic transduction (4, 34). Illum and coworkers (35) investigated the interaction of chitosan microspheres, using turbidimetric measurements and adsorption studies of mucin to the microspheres.

Fig. 2 Experimental setup to measure the force of detachment of mucoadhesive polymer films from mucosal tissue.

Fig. 3 Experimental setup to study the intestinal transit of mucoadhesive microspheres in a chronically isolated loop. (Adapted from Ref. 21.)

Microscopic visualization techniques have also been used to investigate mucus–polymer interactions (36–39). Transmission electron microscopy was used by Fiebrig et al. (36), whereas different microscopical techniques were used by Lehr et al. (37) for the visualization of mucoadhesive interfaces. Transmission electron microscopy in combination with near-field Fourier transform infrared microscopy (FTIR) has been shown to be suitable for investigating the adhesion-promoting effect of polyethyleneglycol added in a hydrogel (38). Moreover, scanning force microscopy may be a valuable approach to obtain information on mucoadhesion and specific adhesion phenomena (39).

THE MUCOSAL ROUTES OF DELIVERY

Buccal Route

The buccal route of drug administration is the most widely used method for application of mucoadhesive delivery systems. Both for local treatment of inflammation (i.e., aphthae) and for rapid absorption of compounds (nitroglycerin), formulation technologies have employed the buccal route for over two decades, and sublingual or gingival

dosage forms are already established in the market (8) (Table 2).

Oral mucosae are composed of multiple layers of cells, which show various patterns of differentiation dependent on the functions of different regions in the oral cavity (40). The oral mucosa is covered by a stratified, squamous epithelium, and three different types of mucosa can be distinguished: the masticatory, the lining, and the specialized mucosa. Blood supply to the oral cavity tissues is delivered via the external carotid artery, which branches to the maxillary lingual and facial artery. There are no mucus-secreting goblet cells in the oral mucosa, but mucins are found in human saliva. These mucins are water-soluble and form a gel of 10–200- μm thickness. Saliva, mainly composed of water (99%), is continuously secreted in the oral cavity and exists as a film with a thickness of 0.07–0.1 mm (40).

In the 1980s, Machida and Nagai (41) evaluated spray dosage forms based on hydroxypropyl cellulose (HPC) for the delivery of beclomethasone to treat recurrent and multiple aphthae. Previously a double-layered tablet of HPC and Carbopol 934P was introduced in the market for the treatment of aphthous stomatitis (41).

Bouckaert et al. (42) tested buccal tablets of miconazole based on modified starch–polyacrylic acid

Table 2 Drug products available for buccal and/or sublingual application using mucoadhesive polymers

Drug	Therapeutic area	Product names
Nitroglycerin	Angina pectoris	Suscard, Cardilate, Nitrobid, Nitromex, Nitrong
Isosorbide mononitrate	Angina pectoris	Imdur, Isordil, ISMO
Buprenorphine	Analgesia	Temgesic, Buprenex
Nicotine	Smoking cessation	Nicotinelle, Nicorette
Ergotamine	Migraine	Ergostat, Ergomar
Methyl testosterone	Hypogonadism, delayed puberty	Oroton Methyl, Testred, Virilon
Lorazepam	Anxiety, insomnia	Ativan

(Adapted from Ref. 8.)

mixtures. Although these tablets showed different mucoadhesion properties in vitro, no significant differences in the salivary content of miconazole could be observed in human volunteers.

Lee and Chien (43) evaluated mucoadhesive devices of a bilayer type, consisting of a fast-release layer containing polyvinylpyrrolidone (PVP) and a sustained-release layer of Carbopol 934P and PVP for prolonged delivery of luteinizing hormone-releasing hormone (LHRH) onto the porcine gingival and alveolar mucosa for 24 h. This device contained also an absorption enhancer (sodium cholate) and cetylpyridinium chloride to protect LHRH from degradation by microflora. The LHRH permeation appeared to increase by raising the loading of LHRH or enhancer in the fast-release layer. The formulation of the devices could be varied to achieve specific rates of transmucosal peptide drug permeation.

Nair and Chien (44) compared patches and tablets of different polymers (sodium carboxymethylcellulose, carbopol, polyethylene oxide, polymethyl vinyl ether–maleic anhydride, tragacanth) regarding their release characteristics of four drugs (chlorheximide, clotrimazole, benzocaine, and hydrocortisone). They observed sustained release of all four compounds from the mucoadhesive tablets, but only two of the active compounds, chlorheximide and clotrimazole, could be released in a controlled manner from the mucoadhesive patches.

Buccal bilayer devices (films and tablets) are comprised of a drug-containing mucoadhesive layer and a drug-free backing layer (45). The former consists of chitosan, free or cross-linked by an anionic polymer (polycarbophil, sodium alginate, gellan gum), and the latter of ethylcellulose. The in situ cross-linking of chitosan by polycarbophil gives tablets that exhibit controlled swelling, drug release, and adequate mucoadhesion to bovine sublingual mucosa.

The periodontal pocket is another site for drug delivery in the oral cavity. Needleman et al. (46) investigated three mucoadhesive polymers (cationic chitosan, anionic

xanthan gum, neutral polyethylene oxide) in vitro, using organ cultures, and in vivo in patients on their periodontal and oral mucosa. Of the polymers studied, chitosan displayed the longest adhesion in vitro and on the periodontal pockets, and the shortest adhesion on oral mucosa.

Nasal Route

The nasal route of drug administration is the most suitable alternative of delivery for poorly absorbable compounds such as peptide or protein drugs. The nasal epithelium exhibits relatively high permeability, and only two cell layers separate the nasal lumen from the dense blood-vessel network in the lamina propria. The respiratory epithelium is the major lining of the human nasal cavity and is essential in the clearance of mucus by the mucociliary system. This epithelium is composed of ciliated and nonciliated columnar cells, goblet cells, and basal cells. The respiratory epithelium is covered by a mucus layer, which can be divided into two distinctive layers (the periciliary layer and a more gel-like upper layer). The periciliary layer consists of a liquid of lower viscosity. Mucus is secreted from goblet cells as highly condensed granules by exocytosis. The mucus layer is propelled by the cilia toward the nasopharynx, and the function of the mucociliary clearance is to remove foreign substances and particles from the nasal cavity, preventing them to reach the upper airways (47).

Various structurally different mucoadhesive polymers were tested for their ability to retard the nasal mucociliary clearance in rats (48). Methylcellulose, sodium carboxymethyl cellulose, hydroxypropyl methylcellulose, chitosan glutamate, Carbopol 934P, polyethylene oxide 600K, and Pluronic F127 were applied in gel form, and their clearance was measured using microspheres labeled with a fluorescent marker incorporated into the formulation. The clearance rate of each polymer gel was found to be lower than that of a control microsphere suspension, resulting in

an increased residence time of the gel formulations in the nasal cavity. Methylcellulose (3%) gel gave the longest nasal residence time, whereas a Carbopol 934P (0.2%) aqueous gel was the least effective.

Illum et al. (49) evaluated chitosan solutions as delivery platforms for nasal administration of insulin to rats and sheep. They reported a concentration-dependent absorption-enhancing effect with minimal histological changes of the nasal mucosa in all concentrations applied.

Oechslein et al. (50) studied various powder formulations of mucoadhesive polymers for their efficacy to increase the nasal absorption of octreotide in rats. Although chitosan showed the highest water uptake (chitosan > microcrystalline cellulose > semicrystalline cellulose \gg pectin = hydroxyethyl starch = alginic acid = Sephadex G25), the highest peptide drug bioavailability was found after coadministration of alginic acid and Sephadex G25 powders (4.1 and 5.56%, respectively). The authors concluded that the calcium-binding properties of the polymers used correlated better with the increased octreotide bioavailability.

Nakamura et al. (51) studied the adhesion of water-soluble and neutral polymers, hydroxypropyl cellulose (HPC), xanthan gum (XG), tamarind gum (TG), and polyvinyl alcohol (PVA) to nasal mucosa in vitro and in vivo. The polymers, mixed with a dye, were applied as powders to the nasal cavity of rabbits, and the remaining dye residue was determined at 2, 4, and 6 h after nasal instillation with a thin fiberscope. The polymer XG showed the longest residence time of the dye in the cavity, followed by TG, HPC, and PVA in decreasing order. For the mixture XG and XG-PVA (2:8), some residue of dye could still be observed 6 h after administration. The order of adhesion of these polymers to agar plates in vitro agreed with that of their mucoadhesion in vivo. Illum et al. (52) introduced bioadhesive microspheres for nasal delivery of poorly absorbable drugs. Radiolabelled microspheres made from diethylaminoethyl (DEAE)-dextran, starch microspheres, and albumin microspheres were administered to human volunteers and appeared to be cleared significantly slower than solutions or nonmucoadhesive powder formulations. However, starch or hyaluronic acid microspheres significantly increased the absorption of peptide drugs from nasal mucosa (53).

Nakamura et al. (54) described a microparticulate dosage form of budesonide, consisting of novel bioadhesive and pH-dependent graft copolymers of polymethacrylic acid and polyethylene glycol, resulting in elevated and constant plasma levels of budesonide for 8 h after nasal administration in rabbits.

Fig. 4 The nasal clearance of bioadhesive formulations and a control in human volunteers. DTPA = diethylenetriaminepentaacetic acid. (From Ref. 55.)

Recently, starch and chitosan microspheres as well as chitosan solutions were tested for their clearance characteristics in human volunteers using gamma scintigraphy (55). The results revealed a 4-, 3-, and 2-times longer clearance half-life (compared to controls) for chitosan microspheres, starch microspheres, and chitosan solutions (Fig. 4). These observations support the hypothesis that chitosan delivery systems can reduce the rate of clearance from the nasal cavity, thereby increasing the contact time of the delivery system with the nasal mucosa and providing the potential for raising the bioavailability of drugs incorporated into these systems.

Ocular Route

The ocular route is used mainly for the local treatment of eye pathologies. Absorption of drugs administered by conventional eyedrops can result in poor ocular bioavailabilities (2–10%). This is due to the limited area of absorption, the lipophilic character of the corneal epithelium, and a series of elimination factors that reduce the contact time of the medication with the corneal surface, such as drainage of instilled solutions, lacrimation, and tear turnover and tear evaporation (56).

The first structure encountered by an ocular dosage form is the precorneal tear film, consisting of three layers:

Outer layer, oily and lipid, mainly prevents tear evaporation.

Middle layer, which is an aqueous salt solution layer, and Inner layer, a mucus layer secreted by the conjunctiva goblet cells and the lacrimal gland. This layer is important for wetting the corneal and conjunctival epithelia. The ocular membranes comprise the cornea (not vascularized) and the conjunctiva (vascularized). The corneal epithelium consists of five or six layers of nonkeratinized squamous cells, and it is considered to be the major pathway for ocular drug penetration (57).

The following types of mucoadhesive preparations have been evaluated for ocular drug delivery: hydrogels, viscous liquids, solids (inserts), and particulate formulations (57). Hui and Robinson (58) introduced hydrogels consisting of cross-linked polyacrylic acid for ocular delivery of progesterone in rabbits. These preparations increased progesterone concentrations in the aqueous humor four times over aqueous suspensions.

Davies et al. (59) compared the precorneal clearance of Carbopol 934P to that of an equiviscous nonmucoadhesive PVA solution and phosphate buffered saline (PBS) using lacrimal dacryoscintigraphy in the rabbit. The precorneal retention of the Carbopol 934P was shown to be significantly longer than that of PVA, which, in turn, was significantly longer than that of PBS. In the same study, Carbopol 934P solution produced a significant increase in bioavailability of pilocarpine as compared to PVA and PBS. The same authors (60) described phospholipid vesicles coated with Carbopol 934P or Carbopol 1342 (a hydrophobic modified Carbopol resin). The mucoadhesive polymer-coated vesicles demonstrated substantially enhanced precorneal retention compared to noncoated vesicles at pH 5. However, the polymer-coated vesicles did not increase the ocular bioavailability of entrapped tropicamide compared to noncoated vesicles and aqueous solutions.

Lehr et al. (61) investigated two gentamicin formulations of polycarbophil (neutralized vs. nonneutralized) to pigmented rabbit eye. Both polymeric formulations doubled the uptake of gentamicin by the bulbar conjunctiva.

Saettone et al. (62) evaluated low viscosity polymers (polygalacturonic acid, hyaluronic acid, carboxymethyl-amylose, carboxymethylchitin, chondroitin sulfate, heparan sulfate, and mesoglycan) as potential mucoadhesive carriers for cyclopentolate and pilocarpine in a study of their influence on miotic activity in rabbits. Small but significant increases in bioavailability were observed and a

correlation was found between the bioavailability of the two drugs and the mucoadhesive bond strength of the polymers investigated.

Calvo et al. (63) studied chitosan- and poly-L-Lysine (PLL)-coated poly- ϵ -Caprolactone (PECL) nanocapsules for ocular application. In comparison with commercial eyedrops, the systems investigated (uncoated, PLL-coated, and chitosan-coated nanocapsules) significantly increased the concentrations of indomethacin in the cornea and aqueous humor of rabbit eyes. The chitosan-coated formulation doubled the ocular bioavailability of indomethacin over the uncoated particles, whereas the PLL coating was ineffective. The authors concluded that the specific nature of chitosan was responsible for the enhanced indomethacin uptake and not the positive surface charge. Both the PLL- and chitosan-coated nanocapsules displayed good ocular tolerance (63).

A recent approach to ocular inserts was presented by Chetoni et al. (64) in a study of cylindrical devices for oxytetracycline, made from mixtures of silicone elastomer and grafted on the surface of the inserts with an interpenetrating mucoadhesive polymeric network of polyacrylic acid or polymethacrylic acid. The inserts were tested for drug release and retention at rabbit eyes. It was shown that some of the inserts are able to maintain prolonged oxytetracycline concentrations in the lacrimal fluid for 36 h.

Vaginal Route

The vaginal route is considered to be suitable for the local application and absorption of therapeutics like estrogens for hormone replacement therapy or contraception. Systemic absorption of peptide drugs such as LHRH agonists and calcitonin can also be achieved (65).

The vagina offers a substantial area for drug absorption because numerous folds in the epithelium increase the total surface area. A rich vascular network surrounds the vagina whereas the vaginal epithelium is covered by a film of moisture consisting mainly of cervical mucus and fluid secreted from the vaginal wall.

Conventional vaginal delivery systems include tablets, foam gels, suspensions, and pessaries. Mucoadhesive gel formulations based on polycarbophil have been reported to remain 3–4 days at the vaginal tissue, providing an excellent vehicle for the delivery of progesterone and nonoxynol-9 (66).

The benzyl ester of hyaluronic acid (HYAFF 11) is a highly mucoadhesive polymer which can be processed into microspheres. Such microspheres containing salmon calcitonin were intravaginally administered to rats as a dosage form for the prevention of ovariectomy

osteopenia (65). In recent studies, HYAFF 11–salmon calcitonin microspheres were formulated as single-dose pessaries, resulting in sustained plasma concentrations of calcitonin (67).

Gastrointestinal Route

The peroral route represents the most convenient route of drug administration, being characterized by high patient compliance. The mucosal epithelium along the gastrointestinal tract varies. In the stomach the surface epithelium consists of a single layer of columnar cells whose apical membrane is covered by a conspicuous glycocalyx. A thick layer of mucus covers the surface to protect against aggressive luminal content. This site of the tract is of minor interest for drug delivery since the low pH and the presence of proteolytic enzymes make the stomach a rather hostile environment. However, there are examples of dosage forms specially designed to be retained in the stomach such as some gastroretentive systems consisting of mucoadhesive hydrogels (68). Akiyama et al. (69) evaluated microspheres for prolonged residence time in the gastrointestinal tract of rats. They prepared two types of polyglycerol fatty acid ester (PGEF)-based microspheres, Carbopol 934P-coated microspheres, and Carbopol 934P-dispersion microspheres. Significantly longer residence times were observed after administration of the dispersion-microspheres than with the coated ones. Additionally, it was shown that the microspheres were retained in the stomach of the animals.

The small intestine is characterized by an enormous surface area available for the absorption of nutrients and drugs. This large area is formed by crypts and villi. The intestinal epithelium consists of a single layer of three types of columnar cells: enterocytes, goblet cells, and enteroendocrine cells. The enterocytes are linked to each other by tight junctions and desmosomes. The goblet cells are mucin-producing unicellular glands intercalated between the enterocytes. The enteroendocrine cells are scattered between the enterocytes and goblet cells and release hormones that can modify the local environment or influence the intestinal motility. At the terminal ileum, the Peyer's patches, a particular specialization of the gut-immune system, are located. This domain contains the M cells, which are specialized in endocytosis and processing luminal antigens. The large intestine (colon) has the same cell populations as the small intestine, and its main function is the absorption of water and electrolytes. The role of mucus in the intestine is to facilitate the passage of food along the intestinal tract and to protect the gut from bacterial infections (70).

In the past decade several difficulties have been encountered in the design of successful mucoadhesive delivery systems for peroral applications. The reasons may be due to shortcomings of the mucoadhesive properties of the polymers or to the peculiar physiological limits of the digestive tract, soluble mucins, and shed-off mucus, food, or other contents of the intestinal lumen which would inactivate the mucoadhesive properties of the delivery system before having reached the absorbing membrane. Furthermore, the adhesion of the delivery system can last as long as the gel-state mucus itself remains attached to the intestinal mucosal tissue. Mucus turnover is continuously removing the mucus gel layer attached to the epithelium by a steady-state process (71).

The failure in increasing residence time of mucoadhesive systems in the human intestinal tract has led scientists to the evaluation of multifunctional mucoadhesive polymers. Research in the area of mucoadhesive drug delivery systems has shed light on other properties of some of the mucoadhesive polymers. One important class of mucoadhesive polymers, poly(acrylic acid) derivatives, has been identified as potent inhibitors of proteolytic enzymes (72–74). The interaction between various types of mucoadhesive polymers, and epithelial cells has a direct influence on the permeability of mucosal epithelia by means of changing the gating properties of the tight junctions. More than being only adhesives, some mucoadhesive polymers can therefore be considered as a novel class of “multifunctional macromolecules” with a number of desirable properties for their use as delivery adjuvants (72, 75).

Lueßen et al. (73, 74) evaluated the mucoadhesive polyacrylates, polycarbophil and Carbopol 934P, for their potency to inhibit intestinal proteases. These polymers are able to inhibit the activities of trypsin, α -chymotrypsin, and carboxypeptidase A and B as well as of cytosolic leucine aminopeptidase. Carbopol 934P was found to be more efficient in reducing proteolytic activity than polycarbophil (74). The pronounced binding properties of polycarbophil and Carbopol 934P for bivalent cations, such as zinc and calcium, were demonstrated to be a major reason for the observed inhibitory effect. These polymers have been shown to remove Ca^{2+} and Zn^{2+} , respectively, from the enzyme structures, thereby inhibiting their activities. Carboxypeptidase A and α -chymotrypsin activities were observed to be reversible upon the addition of Zn^{2+} and Ca^{2+} ions, respectively. Therefore, it was concluded that polyacrylates are promising excipients to protect peptide drugs from intestinal degradation. In vitro studies, using the Caco-2 cell intestinal epithelium model, showed that Carbopol 934P was able to substantially increase the transport of a macromolecular paracellular

fluorescent marker (dextran) and the peptide drug 9-desglycinamide, 8-L-arginine vasopressin (76).

Carbopol 934P and chitosan gels were also tested in vivo for their ability to increase the absorption of the peptide analog buserelin when administered intraduodenally in rats (77). Both polymers increased the absorption of the peptide significantly, probably due to both permeation-enhancing and enzyme-inhibition properties; mucoadhesion played a secondary role. Chitosan was found to remarkably increase the peroral bioavailability of the peptide in comparison to Carbopol 934P (77), indicative of a more specific effect of chitosan with the tight junctions, than previously suggested by Artursson et al. (78).

Chitosan and chitosan salts, however, lack the advantage of good solubility at neutral pH values. They aggregate in solutions at pH values above 6.5, and recent studies have shown that only protonated chitosan (i.e., in its uncoiled configuration) can trigger the opening of the tight junctions, thereby facilitating the paracellular transport of hydrophilic compounds (79). This property implies that chitosan can be effective as an absorption enhancer only in a limited area of the intestinal lumen where the pH values are close to its pK_a . For this reason, chitosan and its salts may not be suitable carriers for targeted peptide drug delivery to specific sites of the intestine, for instance, the jejunum or ileum. To overcome this problem the chitosan derivative *N,N,N*-trimethylchitosan chloride (TMC) has been synthesized and characterized (80). This quaternized chitosan shows higher aqueous solubility than chitosan in a much broader pH range. Chitosan HCl and TMCs of different degrees of trimethylation were tested for enhancing the permeability of the radiolabelled marker ^{14}C -mannitol in Caco-2 intestinal epithelia at neutral pH values (for instance, pH 7.2). Chitosan HCl failed to increase the permeation of these monolayers and so did TMC with a degree of trimethylation of 12.8%. However, TMC with a degree of trimethylation of 60% significantly increased the permeability of the Caco-2 intestinal monolayers, indicating that a threshold value at the charge density of the polymer is necessary to trigger the opening of the tight junctions (81). Because of the absence of significant cyto- and ciliotoxicity, TMC polymers (particularly with a high degree of trimethylation) are expected to be safe absorption enhancers for improved transmucosal delivery of peptide drugs (82).

In recent studies, both in vitro (Caco-2 cells) and in vivo in rats, TMC with a degree of trimethylation of 60% was proven to be an excellent intestinal absorption enhancer of the peptide drugs buserelin and octreotide. The observed absolute bioavailability values were 13 and 16% for buserelin and octreotide, respectively (83)

Fig. 5 Intestinal absorption of octreotide acetate in rats using mucoadhesive polymers. (From Thanou et al., unpublished data.)

(unpublished data; Fig. 5). Permeation-enhancing effects were more responsible for these increased bioavailabilities, rather than the mucoadhesive properties of the TMC polymers. Nevertheless, mucoadhesion is a prerequisite for these polymers in order to further act as absorption enhancers.

Mucus also appears to be a barrier to the permeation enhancing effect of polymeric or monomeric absorption enhancers. In the aforementioned TMC studies, the enhancement effect (enhancement ratio = permeation rate of the drug in the presence of polymer vs. permeation rate of the drug alone) was higher in vitro (Caco-2 cells; no mucus secretion) than the absorption enhancement in vivo. Meaney and O'Driscoll (84) studied the effect of mucus on the permeation properties of a micellar system consisting of sodium taurocholate in a coculture of Caco-2 and Ht29GlucH (mucin-secreting) cells. They found that the effect of bile salts on the permeation of hydrophilic paracellular markers was increased in the cocultures that were pretreated with the mucolytic compound *N*-acetylcysteine.

Bernkop-Schnürch (85) prepared a series of conjugates of protease inhibitors (pepstatin, Bowman-Birk, chymostatin, elastatinal, antipain bacitracin) and/or EDTA to three different types of polymers (carboxymethyl cellulose, polyacrylic acid, and chitosan). In addition to their mucoadhesive properties, most of these conjugates exhibited enzyme-inhibitory properties. Furthermore, the toxicity of these protease inhibitors was reduced by being covalently bound to the polymers. Chitosan-EDTA conjugates have proven to be potent inhibitors of the zinc-containing proteases as well as to be strong mucoadhesives (86).

In order to design highly mucoadhesive platforms for peroral drug delivery, Bernkop-Schnürch et al. (87) proposed thiol groups-bearing polycarboxophil modifications,

based on the mucolytic activity of thiols caused by disulfide exchange reactions between mucin glycoproteins and the mucolytic agent. Polycarbophil–cysteine conjugates appeared to exhibit superior mucoadhesiveness compared to polycarbophil itself, due to improved cohesion and rapid hydration of the gels. However, again mucus turnover is still the limiting factor of adhesion to the cell surfaces.

All the aforementioned polymers have been evaluated mainly for application in the intestine. Finally, the last part of the gastrointestinal tract, the rectum, should also be mentioned as a suitable site for delivery and fast absorption of therapeutics. Kim et al. (88) developed an in situ gelling and mucoadhesive acetaminophen liquid suppository prepared with poloxamers and sodium alginate. It was found that this particular formulation of acetaminophen in humans resulted in shorter T_{\max} and higher maximum plasma concentrations of drug (C_{\max}) than the conventional acetaminophen suppositories.

Suppositories are the preferable dosage form for patients that experience nausea. Yahagi et al. (89) evaluated a mucoadhesive suppository consisting of Witepsol H-15 and 2% Carbopol 934P for rectal delivery and absorption of the anti-emetic drug ramosclron hydrochloride (serotonin antagonist) in rabbits. These suppositories increased the $AUC_{(0-24h)}$ 2.5 times and prolonged the residence time compared to suppositories without mucoadhesive polymer. The anti-emetic effect of the formulation was tested in ferrets, and it was found that the Carbopol 934P-containing suppositories had the same effect as intravenous administration. This formulation was suggested as a once-a-day dosage form for the treatment of chemotherapy-induced nausea.

TRENDS AND PERSPECTIVES

In this article a number of polymer modifications have been described as novel drug delivery platforms, being second-generation mucoadhesive hydrogels. These polymers, both as safe absorption enhancers (75) or as improved mucoadhesive hydrogels, are the most recent developments in mucoadhesive delivery platforms for intestinal absorption of drugs.

Another trend observed during the past decade was the coating of liposomes with mucoadhesive polymers. Liposomes are coated with chitosan, long-chain PVA, and polyacrylates bearing a cholesteryl group (90). Chitosan-coated liposomes showed superior adhesion properties to rat intestine in vitro than the other polymer-coated liposomes. In vivo, chitosan-coated liposomes

containing insulin substantially reduced blood glucose levels after oral administration in rats, which were sustained up to 12 h after administration (90).

Another type of novel mucoadhesive formulations was suggested to be submicron emulsions (o/w), bearing droplets coated with Carbopol 940. These formulations have been shown to generate a 12-fold enhancement in rats in the oral bioavailability of the antidiuretic peptide drug desmopressin (91).

Specific adhesion approaches also show promise. The more specific bindings of plant lectins, mussel glue protein, and K99-fimbriae have been suggested as an alternative to the classical nonspecific mucoadhesive hydrogels. Tomato lectins were found to bind specifically onto both isolated porcine enterocytes and Caco-2 cells with the same affinity (92). However, lectin binding was inhibited in the presence of crude porcine gastric mucin, indicative of a marked cross-reactivity. Irache et al. (93) investigated three different plant lectins conjugated to latex, tomato lectin, *Asparagus pea* lectin, and *Mycoplasma gallisepticum* lectin. The extent of interactions of these three lectin–latex conjugates decreased from the duodenum to the ileum, when tested on rat intestinal mucosa without Peyer's patches. However, when mucosa containing Peyer's patches was used, a substantial increase in the interaction of the conjugates with the mucosa was found, which was more pronounced for the mycoplasma and asparagus lectins than for the tomato lectin (93).

A natural example of mucoadhesion can be the colonization of the small intestine by *Escherichia coli* strains mediated by cell-surface antigens called fimbriae (94). Fimbriae are long, thread-like protein polymers found on the surface of many bacterial strains. They enable bacteria to adhere to the brush border of epithelial cells. A special fimbriae antigen, K99-fimbriae, has been isolated from *E. coli* and bound to polyacrylic acid. The conjugate was tested by a hemagglutination assay for its ability to bind to equine erythrocytes, which have the same K-99-receptor structures as gastrointestinal epithelial cells. A 10-times stronger retention of erythrocytes was observed for the matrix-bound K-99 antigen than for the matrix-bound ovalbumin (94).

Mussel adhesive protein (MAP) is a 130-kDa protein produced by the blue mussel (*Mytilus edulis*), which provides strong adhesion to submerged surfaces. MAP films were prepared by drying and stored under nitrogen atmosphere. These films showed twice the adhesion strength of polycarbophil when tested on porcine duodenum in vitro (95).

All these examples of the applications of mucoadhesive polymers demonstrate that the use of mucoadhesive hydrogels is a powerful strategy to improve the absorption

of therapeutics across mucosal epithelia. With respect to buccal, nasal, or ocular delivery of drugs, the use of such carriers has already been successfully established. However, the application of the mucoadhesive polymers in the gastrointestinal tract is still waiting for a breakthrough. Specific-binding principles may be applied in the near future to design a third generation of mucoadhesive polymers for application in the gastrointestinal tract.

MONOCLONAL ANTIBODIES FOR DRUG DELIVERY

John B. Cannon

Ho-Wah Hui

Abbott Laboratories, Abbott Park, Illinois, U.S.A.

Pramod K. Gupta

TAP Pharmaceuticals, Deerfield, Illinois, U.S.A.

INTRODUCTION

The selective delivery of drugs to their site of action should increase their therapeutic effectiveness while minimizing unwanted side-effects. In the early 1900s, Paul Ehrlich proposed the potential use of antibodies as carriers of biological agents to the target sites, thus inventing the “magic bullet” concept. With the development of hybridoma technology, it is now possible to produce virtually unlimited quantities of homogenous antibodies having a defined specificity, that is, monoclonal antibodies (MoAbs), which have potential to fulfill Ehrlich’s vision. While MoAbs have found use in sensitive diagnostic tests, the therapeutic use of MoAbs and their conjugates are only beginning to realize the promise that was predicted with the advent of the core technology (1–5).

Basic Terminology

In simplistic terms, an antibody is an immunoglobulin synthesized by the body’s immune system in response to a foreign molecule (an antigen, i.e., an antibody generator), and is capable of binding the antigen with high specificity. In general, an antigen must have a relatively large molecular weight (>1000) to elicit an immune response; smaller molecules can be made to be antigenic by coupling it to a suitable macromolecule, e.g., albumin.

An antibody is a Y-shaped molecule (Fig. 1) (6), and contains two light chains and two heavy chains joined together by disulfide bonds. Each of the heavy chains also contains a carbohydrate residue. The bottom “trunk” portion of the antibody molecule is known as the constant (Fc) region because its amino acid sequence is often similar within a given animal species. The upper “arms”, the antigen binding regions (Fab), are known as the variable regions because its amino acid sequence is determined by the antigen responsible for its formation.

The variable region, in turn, has several “hypervariable” regions, also known as the “complementarity determining regions” (CDR), which show greater variability than the rest of the variable region.

Antibodies can be classified in the following:

Polyclonal Antibodies: After an antigen is injected into an animal by a regimen designed to induce an optimal immune response, serum can be collected from the animal and the immunoglobulin fraction isolated. This “antisera” is enriched with antibodies specific for the original antigen. Because a large number of lymphocytes are involved in the production of the antisera, antibodies produced by this classical method are called polyclonal.

Monoclonal Antibodies: An antibody is called “monoclonal” when each immunoglobulin is produced by a single clone of cells and hence is identical to every other molecule in the preparation, in terms of heavy as well as light chain structure. Thus they are highly specific and offer more consistent efficacy and predictable toxicity in vivo than the polyclonal counterparts (7).

Antibody Fragments: The earliest MoAbs examined in animal and clinical studies were murine antibodies. Because of their nonhuman origin, they are immunogenic in humans, i.e., they have a tendency to elicit a human antimouse antibody (HAMA) response. They also have been shown to have much shorter clearance rates than human MoAb’s. One approach to overcome these problems has been to cleave the antibody (e.g., by papain digestion) into its respective Fc and Fab fragments (Fig. 2a) (8). In general, the Fab fragments are less immunogenic than the corresponding intact antibodies, and their smaller molecular size may facilitate penetration into tumor tissue (9) and result in a longer half-life. However, they can lose some of their antigen binding capacity, and in some cases the

Fig. 1 Diagram of an monoclonal antibody molecule. (Adapted from Ref. 6.)

therapeutic effect may depend on the Fc portion of the antibody.

Chimeric Antibodies: The obvious solution to the problems encountered with murine antibodies would be to clone a fully human antibody. However, human hybridomas required for human MoAb production have been notoriously difficult to culture, and it may be impossible to obtain many of the appropriate antibodies. A strategy that has been devised to overcome the HAMA problem of murine MoAbs is by constructing a chimeric antibody (Fig. 2b), which contains the Fc region of human IgG, but the Fab regions are murine in origin. These can be made chemically by joining murine Fab fragments to the Human Fc fragment, but the preferred method is to use recombinant DNA technology, as detailed in a later section.

Humanized Antibodies: Although human studies have suggested that chimeric antibodies elicit less HAMA response than murine antibodies, they are still immunogenic due to their murine regions (generally about 30% of the total molecule). A major advance was achieved when it was recognized that only a small portion of an antibody molecule was actually responsible for antigen binding, in fact only the CDR regions. One can envision construction of a "humanized" antibody in which the majority of the antibody framework is human in origin, but the CDR's are murine (Fig. 2c). Synthesis of such humanized antibodies have been successfully achieved by recombinant DNA technology, and can have up to

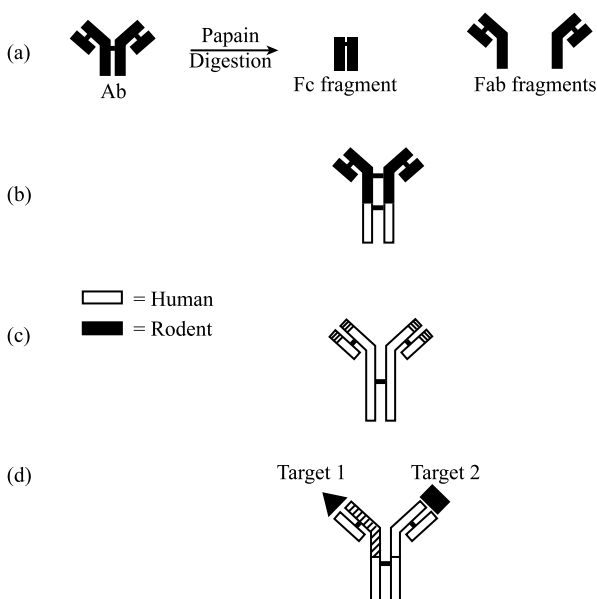

Fig. 2 Diagram of the most important MoAb constructs used clinically: a) antibody fragments; b) chimeric antibody; c) humanized antibody; d) bispecific antibody. (Adapted from Ref. 8.)

95% homology with human antibodies. (Some confusion in the literature exists regarding the terminology for humanized and chimeric antibodies, in that some authors use the terms interchangeably.)

Bispecific Antibodies: Antibodies can be constructed using recombinant DNA technology in which each of the two arms are specific for two different antigens (Fig. 2d). For example, bispecific MoAbs reactive with CD15 antigen, and composed of Fab fragments of anti-CD64 MoAb 32 and a whole IgM antimyeloid cell MoAb, PM-81, have been investigated for the therapy of patients with CD15 positive tumors, e.g., acute myelogenous leukemia, small cell carcinoma of the lung, colorectal cancer, and breast carcinoma (10).

Immunoconjugate: For MoAb targeted drug delivery, a drug is bound covalently to an antibody that is chosen to target it to the desired site of action. The resulting immunoconjugate may contain a spacer between the drug and antibody, or a polymer to increase the number of drug molecules that can be bound to each antibody. Another possibility is a radioimmunoconjugate, which is designed to be concentrated at the target site by the targeting antibody, allowing the radiation from the bound radioisotope to exert its cytotoxic affect. Alternatively, the drug can be incorporated noncovalently into a liposome or microsphere to which the targeting antibody

is bound to the surface, yielding an immunoliposome or immunomicrosphere, respectively.

PREPARATION AND MANUFACTURE OF ANTIBODIES AND ANTIBODY-BASED DELIVERY SYSTEMS

Manufacture

Every B-lymphocyte in an animal expresses an antibody of only one specificity. After it is triggered to differentiate, the B-cell turns into a plasma cell with the cytoplasmic machinery to synthesize and secrete large quantities of its own unique immunoglobulin. To prepare MoAbs, usually a mouse is immunized with the antigen of interest, e.g., human tumor cells. When an immune response ensues, B-lymphocytes from the spleen or lymph nodes of the animal are harvested in a single cell suspension. These cells are then fused with myeloma cells from the same species, using a fusogenic substance (e.g., polyethylene glycol) or electric current (11). Mutant myeloma cells are used which are deficient in an enzyme, hypoxanthine guanine phosphoribosyl transferase (HGPRT), which is needed for their survival in the presence of the folic acid antagonist, aminopterin. The resulting fused cells have the cytoplasmic machinery to promote cell division and produce large amounts of immunoglobulin. The cell suspension is then transferred to the wells of a microtiter plate in a medium such as hypoxanthine/aminopterin/thymidine. Only the hybridomas that have acquired the HGPRT from lymphocytes via cell fusion usually survive. The hybrids are cloned by limited dilution to one cell per well so that it is easy to identify an antibody of the desired titer, specificity, and avidity for propagation in mass culture. The cell supernatant is then purified by column or affinity chromatography to harvest the pure antibody.

For chimeric and humanized MoAb the above procedures are modified somewhat. The preferred method for the latter is to use recombinant DNA technology and construct a gene that expresses the chimeric or humanized antibody, by splicing the appropriate DNA sequences together in the plasmid of the hybridoma. Synthesis of such humanized antibodies have also been successfully achieved by recombinant DNA technology; the portions of gene encoding the murine CDR regions are spliced into the gene encoding the human antibody by transfection. Although these constructs proved to be much less immunogenic than murine or chimeric antibodies, early work indicated that they had lower antigen binding

capacity than the original murine MoAb. This was apparently because of the absence of certain residues in the human framework that while not directly involved in antigen binding, are required to retain the CDR regions in the correct conformation. Choice of human framework IgG, which is as homologous as possible with the murine antibody, will aid in this regard. In addition, sophisticated molecular modeling techniques based on X-ray crystallography and computer modeling has been used to identify these required residues, which has allowed introduction of the residues into the framework region by recombinant technology (12).

Due to the increased application of MoAbs in diagnostics and therapeutics, considerable effort has been made to develop technology for the large-scale production of MoAbs. Examples of the currently employed culture systems are hollow-fiber systems, suspensions, solid-phase cell immobilization, perfusion reactor, and encapsulation in semipermeable vesicles (13, 14). The system of choice is dependent on the cell line and on the desired characteristics and quantity of the final product. To increase the mixing efficiency of cell-culture equipments and to provide aeration, several different devices have been designed, e.g., vibromixer, marine propeller, turbine propeller, spinning magnetic bar, magnetic spinner, and airlift (14, 15).

Perfusion systems have also been used for successful scale-up of MoAb production. During the culture period, cell growth occurs exponentially until the cell density reaches a maximum. At that point, the medium needs a continuous supplementation of fresh nutrients and elimination of waste. In perfusion systems, fresh nutrients are supplied and wastes are removed continuously so that the medium meets the physiological needs of the cells. At steady state, the cell concentration is determined by space and other limitations. High cell densities have been achieved by immobilizing the cells in porous ceramic matrices or hollow fiber devices. Intermediate cell densities have been achieved by perfusion reactors with a spin filter, or in a fluidized bed reactor in which the cells are embedded in sponge-like microcarriers (14, 15).

Coupling Methods for Antibody Drug Conjugates

An important part of the design of an antibody-directed drug delivery system is the type of linkage and coupling method between antibody and drug. The drug can be covalently bound to the MoAb directly or through a short spacer, or the two can be conjugated through a linker such as a water-soluble polymer. Alternatively, a carrier such as

a liposome or a polymeric microsphere can be used, wherein the drug is entrapped in or bound to the carrier, and the MoAb is bound to the surface of the carrier. Characteristics that would comprise an ideal antibody directed delivery system could include, preparation by a method that has high efficiency and yield, and is capable of scaleup; high stability of the conjugate, both under shelf storage conditions and in the circulation after injection; and retention of antigen-binding ability of the antibody while it is carrying the drug to the target tissue. Finally, upon reaching the target, either the immunoconjugate itself should have the desired pharmacological effect equivalent to the free drug, or must release free drug or a derivative that is fully efficacious. Although such a system is probably impossible to achieve for most therapeutic applications, a variety of coupling reagents are fortunately available that aid in optimizing the properties of an immunoconjugate.

Amino, sulfhydryl, and carboxyl groups are the most common functional groups on the antibody, carrier, and drug molecules used for coupling. If the drug lacks the desired group, it may be possible to introduce it. For example, as shown in Fig. 3, succinic anhydride (Fig. 3a) can convert an alcohol or amino group to a carboxyl group; 2-iminothiolane (Traut's reagent, Fig. 3b) can convert an amino group to a sulfhydryl.

For linkage of drug to antibody, "classical" protein cross-linking reagents have been used to prepare immunoconjugates. For example, carbodiimide reagents (e.g., dicyclohexyl carbodiimide, DCC, Fig. 3c, and its water soluble analogs) link amino groups with carboxyls via amide bonds. In an "active ester" method, carboxyl groups of the drug are linked to *N*-hydroxy succinimide (NHS, Fig. 3d) in the presence of a carbodiimide to form an active ester derivative of the drug, which then reacts with the amino group of the antibody (16). Linkers such as dextran, allow conjugation of a much larger number of drug molecules with each antibody molecule. Thus, dextran and similar carbohydrate linkers are oxidized with periodic acid (Fig. 3e) to form aldehyde groups, which are then linked to amino groups of drug and antibody with formation of an imine. This product can be stabilized by reduction with sodium cyanoborohydride.

These simple reactions are often not specific enough for efficient immunoconjugate formation. More recently, a number of bifunctional reagents have been developed that are more specific in forming linkages of antibody to drug. Heterobifunctional reagents, which have two different reactive groups at the two ends of the molecule, have become the method of choice for preparation of immunoconjugates. Among the most widely used is

N-succinimidyl 3-(pyridyldithio) propionate (SPDP, Fig. 3f). Generally, the reagent is used to derivatize the drug with a pyridyl disulfide group; reaction of this species with the antibody containing free sulfhydryl groups yields the immunoconjugate. *N*-[6 maleimidocaproyl]oxy]succinimide (EMCS, Fig. 3g) is a reagent that reacts with amino groups at the succinimide end and sulfhydryl groups at the maleimide end. A similar reagent, *N*-[4 maleimidoethoxy succinyl]oxy]succinimide (MESS), has a metabolizable ester linker between the two active functionalities, thus providing a method to control release of free drug (17). Combinations of classical coupling methods with bifunctional reagents have also been used to advantage for preparation of immunoconjugates. For example, a 6 carbon spacer ending in a carboxyl group was introduced into dextran (MW 70,000), and then mitomycin C (MMC) was coupled to the spacer with a carbodiimide. The remaining carboxyl groups of the spacers were modified to amino groups, which were then coupled to MoAb A7 by means of SPDP, with a final MMC/MoAb ratio of 40. The antibody activity of the resulting conjugate was almost equivalent to native MoAb A7, and released free MMC by chemical hydrolysis to maintain cytotoxicity (18). Similarly, Zara et al. modified an IgM against human carcinoma by oxidation of its carbohydrate residues, which were then coupled to a bifunctional reagent, S-(2-thiopyridyl)-L-cysteine hydrazide (TPCH) via the hydrazide. After Ricin A was coupled to the other end of the reagent by a disulfide bond, the immunoconjugate retained full toxin and antibody activity with up to 16 TPCH molecules incorporated per antibody, suggesting that carbohydrate residues of the antibody were not involved in the antigen-binding process (19).

Plasma or intracellular enzymes such as esterases or proteases can potentially degrade immunoconjugate linkages. Glutathione reductase and related enzymes are instrumental in cleavage of disulfide bonds of immunoconjugates. The local pH of the target tissue or of its intracellular environment (e.g., lysosomes) may also increase the rate of release of drug from the immunoconjugate. Thus it is important to consider the possible physiological destinations after injection of the immunoconjugate, and to monitor its degradation under conditions mimicing the biological milieu, which it may encounter. Ideally, an immunoconjugate should be sufficiently stable in the circulation to allow targeting to take place; once the antibody binds to its antigen on the target cell surface, the entire immunoconjugate should be internalized into the cell and be degraded to release free drug or an active derivative. However, for many cell types internalization of the immunoconjugate

Fig. 3 Coupling reagents for conjugation of drugs to monoclonal antibodies, showing the reactions involved.

does not always occur in response to antibody binding. In that case, degradation of the immunoconjugate linkage should be sufficiently rapid to provide high local concentrations of free drug or active derivative for the desired pharmacological response. An advantage of bifunctional reagents is that they allow incorporation of a metabolizable linker into the immunoconjugate, thereby releasing free drug or an active derivative at a predictable rate.

A number of studies have explored coupling methods that allow control of the *in vivo* rate of release of active drug. Kaneko et al. (20) designed hydrazone linkers to release drug at lower pH: free doxorubicin was released from conjugated antibody within 6 h at 37°C at pH 4.5, conditions which mimic the environment of the lysosomes; the particular antibody used was known to be internalized. Similarly, Lavie et al. (21) constructed daunomycin conjugates linked to MoAb L6 via a polylysine and aconitate linkage, such that the conjugate releases free drug at pH 6. Although this antibody is not internalized, the lower pH of tumor tissue was suggested to lead to increased concentrations of free drug in tumors. New heterobifunctional reagents have been reported with greater versatility in release rate. The disulfide bond of SPDP conjugates has been shown to be labile in the circulation and release drug prematurely; an analog, NHS-ATMBA, is up to two orders of magnitude more stable than SPDP conjugates because of steric hindrance around the disulfide bond, and thus leads to more efficient targeting (22). Several new substituted 2-iminothiolane reagents, which exhibit increased stability of the disulfide bond of the resulting immunoconjugate, have also been synthesized (23).

Appropriate choice of spacer can also significantly improve the success of an immunoconjugate. For example, O'Neill and co-workers conjugated *N,N*-bis-(2-chloroethyl)-*p*-phenylenediamine (PDM) to the globulin fraction of rabbit anti-EL4 serum, which reduced the toxicity by as much as 20-fold relative to free drug. However, the conjugate was found to aggregate, making it difficult for clinical applications. Hence poly-L-glutamic acid (PGA) was tried as a spacer and it allowed preparation of a water-soluble PDM-PGA-Ig conjugate in molar ratio of 90:2:1 retaining 66% of the original antibody activity (24).

In the case of immunotoxins and other protein-antibody conjugates, a unique choice exists for their construction, viz. the conjugate can be made entirely by recombinant DNA techniques. This would require splicing the two genes together and expression of the chimeric gene in a monoclonal system. For example, the gene for angiogenin (a human toxin-like molecule) was

fused to the gene for an antitransferrin receptor, and the chimeric gene was introduced into a transfectoma to clone cell lines that secrete the hybrid antibody-angiogenin protein. The conjugate was active as a cytotoxic agent, and the activity was mediated by the transferrin receptors (25). Similar techniques were used to construct a conjugate of urokinase-type plasminogen activator and a humanized antifibrin antibody, resulting in a 12-fold enhancement of fibrinolytic activity of the conjugate relative to the parent (unconjugated) urokinase (26). Construction of an immunoconjugate by this approach has the advantage that once the clones are expressed, the immunoconjugate can be made in one step without chemical modification. Also, a single species is generally produced by this method. It has the disadvantage that generally only a 1:1 or perhaps 2:1 ratio of drug to antibody can be accommodated by the immunoconjugate.

IMMUNOTHERAPY WITH UNCONJUGATED MONOCLONAL ANTIBODIES AND RADIOIMMUNOCONJUGATES

Within the last decade, several unconjugated MoAbs have come to market for treatment of cancer, renal transplantation, and other applications, as shown in Table 1. Results from the clinical trials of these and other MoAbs in development have shown that unconjugated MoAbs are able to kill cancer and other cells. When the circulating MoAb binds to its target antigen, several mechanisms may be initiated that are responsible for the therapeutic effect. One is antibody-dependent cellular toxicity (ADCC), wherein neutrophils, mononuclear phagocytes, eosinophils, natural killer, and T-cells, which have receptors for IgG (Fc), are triggered to mediate cell destruction (27). Also important is complement dependent cytotoxicity (CDC) wherein complement binds to the Fc portion of the MoAb after antigen binding and initiates the complement cascade ending in cell death. MoAb binding to the target antigens on cell surfaces can also act as "blocking" antibodies, interfering with the binding of certain peptides or growth factors needed for cell growth, or elicit a regulatory effect on the metabolism of the cell, especially for B-cell lymphocytes and B-cell lymphomas. The interaction of MoAbs with growth factor receptors (such as transferrin receptors) may also have an antitumor effect via a regulatory mechanism because transferrin is essential for the growth of cells and its receptors are predominantly present on proliferating cells (28).

Table 1 Therapeutic MoAb drug currently marketed

Generic name	Trade name (company)	Type of MoAb	Application(s)
Rituximab	Rituxan (IDEC/Genentech)	Chimeric anti-CD20	Non-Hodgkins lymphoma
Trasuzumab	Herceptin (Genentech)	Humanized anti-HER2	Metastatic breast cancer
Palivizumab	Synagis (Medimmune)	Humanized anti-RSV epitope	Antiviral (Pediatric lower respiratory tract disease)
Muromonab-CD3	Orthoclone OKT3 (Ortho)	Murine anti-CD3	Immunosuppressant (renal transplantation)
Daclizumab	Zenapax (Roche)	Humanized anti-CD25	Immunosuppressant (renal transplantation)
Abciximab	ReoPro (Centocor)	Fab fragment of chimeric anti-7E3	Platelet aggregation inhibitor (Coronary intervention)
Basiliximab	Simulect (Novartis)	Chimeric anti-CD25	Immunosuppressant (renal transplantation)

Among the most successful has been Rituximab (Rituxan). This MoAb binds to the CD20 antigen of B-lymphocytes, which is expressed on >90% of non-Hodgkin's lymphoma B-cells. Upon binding, the Fc region of the MoAb recruits immune effector functions to mediate B-cell lysis, possibly by both CDC and ADCC mechanisms. In a multicenter clinical trial with 166 non-Hodgkin's lymphoma patients, who received 375 mg/m² over 4 doses, the overall response rate was 48% (6% complete, 42% partial). A second study with 37 patients gave similar response rates, and single doses of up to 500 mg/m² were well-tolerated (29).

Trasuzumab (Herceptin) binds to the extracellular domain of a transmembrane protein, human epidermal growth factor receptor 2 (HER2), which is overexpressed in 20–30% of primary breast cancer cells. It is thought to act primarily by ADCC. In a phase III trial, 222 breast cancer patients, who exhibited overexpressed HER2, were dosed weekly with 2 mg/kg trasuzumab after a 4 mg/kg loading dose. There was a 14% overall response (2% complete response and 12% partial response), which appeared to be correlated to the degree of HER2 overexpression. Overall response was much better when trasuzumab was combined with standard chemotherapy (viz., paclitaxel, doxorubicin + cyclophosphamide, or epirubicin + cyclophosphamide): 45% compared to chemotherapy alone (30). Similarly, trasuzumab combined with cisplatin, either in pegylated liposomes or in saline/mannitol solution, was significantly better than either treatment alone in retarding tumor growth in a mouse xenograft tumor model (31).

Some workers have proposed use of anti-idiotypic antibodies as type of "tumor vaccine." In this approach, a MoAb is prepared against a given tumor antigen.

Rather than using it for immunotherapy directly, it is used to inoculate mice, which produces a second antibody against the idiotype site of the original antibody (hence, the anti-idiotypic). After cloning and administration to patients, this anti-idiotypic MoAb would mobilize the patient's own immune system to produce a third antibody (i.e., an anti-anti-idiotypic), that would have the same idiotype of the first antibody and thus bind to the original antigen and lead to cytotoxicity (27). The perceived advantage of the approach is the multiplicative effect of the "vaccine," and it is believed to be more specific and safer than using the antigen itself as a vaccine. When 15 melanoma patients were treated with a mouse anti-idiotypic antibody homologous to a melanoma antigen, 7 patients developed the desired immune response, and there were 3 partial responses (32). Thus, although the approach may be promising, it has to be more fully evaluated to determine its utility.

Although MoAbs have many potential uses for tumor therapy, there are inherent problems associated with this approach: i) Cancer cells are heterogeneous, so those cells that are not recognized by the MoAb can escape and proliferate; ii) Some tumors contain semidead cores with poor circulation and thus cannot be reached by monoclonals; iii) MoAbs can interact with circulating target antigens before reaching their target; iv) Patients can experience possible immunogenic reactions. For these reasons, it has frequently proven more effective to combine MoAb treatment with standard chemotherapeutic agents.

Radioimmunoconjugates are MoAbs to which radio-nuclides have been conjugated, to provide cytotoxic radiation after the MoAb binds to its target antigen. The

isotopes most commonly used are Iodine-131 and Yttrium-90, both of which are β^- emitters having half-lives of 8 and 2.5 days, respectively. The former is covalently bound to tyrosine residues of the MoAb by standard chemical techniques, whereas the latter is chelated to a ligand that has been conjugated to the MoAb by techniques described in the previous section (e.g., diethylenetriaminepentaacetic acid ligand coupled with a mixed anhydride method) (33,34). Radionuclide emissions from both ^{131}I and ^{90}Y can extend to 1–5 mm of their final location, corresponding to several cell diameters. Thus, their chief advantage resides in their ability to kill tumor cells that are poorly accessible and/or antigen-negative. Unlike conventional radiation therapy, radioimmunoconjugates provide continuous radiation from the decay of the radionuclide, which allows less opportunity for the tumor cells to repair sublethal damage (35). Depending on the type of MoAb, the antibody itself may trigger CDC and ADCC mechanisms that supplement the effect of the radionuclide.

Although no radioimmunoconjugates have progressed to the market, a number have been examined in clinical trials. Bexxar (^{131}I -tositumomab) is an anti-CD20 MoAb examined in Phase III trials for non-Hodgkin's lymphoma (36). In an early trial of this radioimmunoconjugate, 19 patients with non-Hodgkin's lymphoma, who had been prescreened for favorable biodistribution of the MoAb, received 234–777 mCi of the ^{131}I -anti-CD20 MoAb. Because this was considered a myeloablative dose, the patients received autologous marrow reinfusion following the therapy. Although adverse effects were substantial due to the high dose of radiation, the regimen resulted in a complete response in 16 patients and a partial response in 2 patients; the MTD in terms of tissue exposure was determined to be ≤ 2700 cGy (37, 38). A Phase II trial with a similar regimen in 21 patients achieved 17 complete responses, with an 81% progression-free survival at 12 months (35).

APPLICATIONS OF MONOCLONAL ANTIBODIES IN DRUG DELIVERY

Principle of Targeting

Several classes of drugs lack specificity for diseased cells; for example, the cytotoxic action of chemotherapeutic agents is directed against any rapidly proliferating cell population. Due to this nonspecificity, many drugs have low therapeutic indices and often cause

serious side effects. One way of circumventing this problem is to deliver the drug in a manner such that it is preferentially localized at the desired site of action, or it predominantly attacks the diseased cells. This process is called targeting. Targeted drug delivery systems can be classified into three categories, viz. passive, physical, or active targeting (39). Passive targeting refers to the natural in vivo distribution pattern of the drug delivery system, which is determined by the inherent properties of the carrier (e.g., hydrophobic and hydrophilic surface characteristics, particle size and shape, surface charge, and particle number). For example, modulation of particle size makes it possible to passively target the lungs or reticuloendothelial system (RES) using particles $>7\text{ }\mu\text{m}$ or $0.2\text{--}7\text{ }\mu\text{m}$, respectively (40).

In physical targeting, some characteristics of the environment are utilized to guide the carrier to a specific site or to trigger selective release of its content at the site. Usually, it is accomplished via an external mechanism, such as induced local hyperthermia (e.g., using thermally sensitive liposomes) or a localized magnetic field (e.g., using magnetically responsive albumin microspheres). In active targeting, the natural disposition pattern of a carrier is modified to target it to specific organs, tissues, or cells. Although cell-specific ligands have been used to target carriers to specific cell types, this approach is probably limited to a small number of tumor types. MoAbs would thus appear to be the more generally applicable mode of active targeting. While the field is less advanced than unconjugated MoAb and radioimmunoconjugates, there has been some success in targeting toxins (i.e., immunotoxins) and drugs (i.e., drug immunoconjugates) using MoAbs as targeting agents.

Toxin Conjugates

Over the last two decades, several toxin proteins like diphtheria toxin and ricin have been conjugated to tumor specific antibodies, with moderate to high degree of success in tumor drug delivery. There are several toxins produced by plants (e.g., ricin, abrin, saporin, and gelonin) or bacteria (e.g., diphtheria toxin and pseudomonas exotoxin) used to construct immunotoxins. These toxins are highly potent, and generally a single toxin molecule is sufficient to lead to cell death (36). Most of the native toxins consist of two chains (e.g., Ricin A and B chains) one of which bind nonspecifically to cell surfaces and the other is responsible for the cytotoxicity. To construct an immunotoxin, the nonspecific binding chain (viz. Ricin B) must be removed or masked, and the

cytotoxic chain (viz. Ricin A) conjugated to a MoAb chemically or by recombinant methods. Most toxins of plant origin exert their cytotoxicity by deactivating the ribosomal protein synthesis, and thus require internalization. A few others do not require internalization and are membrane-acting by a cytolytic mechanism; these include bacterial α -hemolysin, streptolysin, and the equinatoxin of sea anemone (41). In one of the first Phase I trials of an immunotoxin, an antiCD22 MoAb Fab' fragment was conjugated to Ricin A and administered to 15 patients. The MTD was 75 mg/m² and there was a 38% partial response (42, 43). Of the total of 200 patients in 9 clinical trials, which examined a variety of ricin-based immunotoxins, there was only a 3% complete response and a 12% partial response (43). This mediocre success may be due in part to the high inherent immunogenicity of immunotoxins. For ricin-based conjugates, the dose limiting toxicity arises from the vascular leak syndrome, a condition characterized by extravasation of fluid into interstitial space. Clinical trials have also indicated that poorly vascularized tumors are not suitable for immunotoxin therapy (43), perhaps because of their high molecular weight. To be more penetrating and to be less immunogenic, immunotoxins and similar targeting molecules need to be made smaller (44).

Drug Immunoconjugates

Over the last several decades, a number of antitumor agents, including chlorambucil, methotrexate, daunomycin, and doxorubicin conjugated to tumor specific antibodies, have been investigated, with varying degrees of success in tumor drug delivery. The most extensively studied has been a doxorubicin-BR96 immunoconjugate (BMS-182248-1). BR96 is a chimeric MoAb specific for a Lewis antigen found on the surface of tumor cells. The immunoconjugate is formed using an acid-labile hydrazone linkage attached through the thiol groups of the MoAb, with 8 moles of doxorubicin/mole of MoAb. After rapid internalization into antigen-bearing cells, the conjugate is designed to release free doxorubicin from the MoAb hydrazone linkage in the acidic environment of the lysosome (45). When tested in mice with xenografted human lung, breast, and colon carcinomas, there was an 89% and 72% cure rate (tumor reduction to nondetectable levels) in the lung and colon models, respectively. In breast carcinoma xenograft, results were less spectacular, with 10% complete response and 60% partial response. Doxorubicin or MoAb alone gave <1% cures in any of the models (46, 47). In a rat lung carcinoma xenograft model, there was a 94% cure rate, even though, unlike

mice, the Lewis antigen is expressed in normal tissue of rats (46, 47).

Because of the encouraging *in vivo* results, clinical development of this immunoconjugate was initiated. The pH-rate profile was determined using a stability-indicating size-exclusion HPLC assay, and exhibited a maximum stability at pH 7.5. The predominant route of degradation was hydrolysis at the hydrazone linkage to release free doxorubicin, with aggregation being a secondary pathway. This was supported by ELISA assay that demonstrated no loss of conjugate after 1 week of storage at 2–8°C. However, because the stability even at this temperature was insufficient for clinical development, a lyophilized formulation was developed. Formulations that remained amorphous due to the use of sucrose or lactose as lyoprotectant showed the greatest stability, with a shelf life of the lyophilized product of more than 12 months at 2–8°C. (48). In a Phase II study, the BR96 Doxorubicin conjugate (BMS182248-1) was administered to 14 metastatic breast cancer patients. However, there was only 1 partial response (7%), in contrast to doxorubicin alone, which gave 44% response. The toxicity profile of the two regimens was markedly different, with the doxorubicin showing the usual cardiotoxicity and hematologic toxicity, whereas the immunoconjugate showed GI associated toxicity, similar to the Phase I studies. It was proposed that the lack of correlation of the Phase II trial with the preclinical *in vivo* data could be because of the presence of the Lewis antigen at sites in the GI tract. This may act as an "antigen sink," preventing targeting to the tumor tissues and instead exacerbate the GI toxicity (49). Colon and lung cancer models showed better clinical responses than the breast cancer models (46), suggesting that clinical trials in these cancers may be more promising than breast cancer.

Another promising immunoconjugate is CMA-676, which is a conjugate of an anti-CD33 MoAb and calicheamicin, an anticancer drug shown to be 1000-fold more potent than doxorubicin in animal models. A Phase II trial of 39 acute myeloid leukemia patients resulted in 2 patients with complete remission and 7 patients who showed temporary removal of leukemia cells from the blood. CMA-676 is now in pivotal clinical studies in a number of centers in North America and Europe (36).

Preliminary clinical studies with chlorambucil-anti-melanoma globulin conjugates in patients with disseminated diseases have also indicated improvement in patient survival (50). The evaluation of vindesine-anti-CEA antibody conjugates in patients with advanced metastatic cancer (and probably expressing CEA) has

demonstrated positive localization of the conjugate (51). In this study, 8 patients received escalating doses of antibody (1–42 mg) conjugated to 24–1800 μ g vindesine, and no toxicity or hypersensitivity was noticed in any patient (51). However in most instances, the tumor versus normal tissue distribution ratio of antibodies approximated 2:1, and it rarely demonstrated specificity leading to a more desirable ratio like 10:1 (52).

Some studies have demonstrated synergism in anti-tumor response with drug–antibody conjugate. For example, a clinical trial with bronchial carcinoma patients compared chemotherapy with immunochemotherapy. The latter group received chemotherapy immediately prior to the administration of antibodies against a resected portion of the primary tumor. The group receiving chemotherapy alone demonstrated a 60% recurrence rate along with a 41% death rate; however, the immunochemotherapy group demonstrated only a 25% recurrence rate along with a 16% death rate (53).

Bispecific MoAbs composed of anti-CD3 or anti-CD2 MoAb, chemically conjugated to antitumor antibody and coated on lymphokine-activated killer (LAK) cells, have been clinically investigated for the treatment of malignant glioma, lymphoma, and ovarian cancer with encouraging results. In a trial involving malignant glioma therapy, bispecific MoAb-coated LAK cells were injected intracranially following surgical removal of tumor and whole brain irradiation and/or chemotherapy. This resulted in 76% of the patients being tumor-free after 2 years, as opposed to 33% of the patients tumorfree with LAK cell treatment alone (54).

Because of the ability to achieve higher drug–antibody ratios, various water-soluble polymeric carriers have been examined as linking agents in immunoconjugates. For example, encouraging results have been demonstrated with daunomycin conjugated to MoAbs via dextran bridge in rats bearing AH66 hepatoma cells (55). Similarly, MMC was conjugated to an anti- α -fetoprotein MoAb via a human serum albumin carrier in a molar ratio of 30:1:1. Full antibody activity was retained, and the conjugate was 20-fold more cytotoxic than free MMC in vitro and was also more effective than free MMC in tumor-bearing mice (56). Poly(lysine) has also been successfully used as a carrier, e.g., for targeting methotrexate (57) and muramyl dipeptide (58). *N*-(2-hydroxypropyl)-methacrylamide copolymers have been extensively examined as carriers for tumor targeted drug delivery (59, 60). Enzymatically cleavable spacers (e.g., oligopeptides) have been incorporated into these conjugates to allow release of active chemotherapeutic agent (59, 61).

Immunoliposomes

Generally, the antigens expressed by tumor cells are not specific but are merely present in higher ratio than on the normal cells. Hence, systems such as immunoliposomes have been developed to exploit these opportunities, as they are expected to bind to a greater extent to high antigen density tumor cells than to low antigen density normal cells. In immunoliposomes, the number of antibody molecules per liposome can be varied by as much as two orders of magnitude (62). Using egg phosphatidylcholine, cholesterol, phosphatidylserine, and *N*-4-nitrobenzo-2-oxa-1-1,3-diazole phosphatidylethanolamine in molar ratio of 56:33:10:1, unilamellar liposomes with 12–55 antibody molecules per vesicle have been investigated for binding with RDM-4 lymphoma cells with varying antigen density. The increase in the valency of liposomes (i.e. number of antibody molecules per liposome) increased their binding with low as well as high antigen density cells, and thus the low valency immunoliposomes were found to allow better discrimination between target and normal cells (62). An additional advantage of immunoliposomes is that a relatively high drug loading can potentially be accommodated, with the result that a small number of antibody molecules conjugated to the surface of an immunoliposome can deliver many more drug molecules to the target than is otherwise possible. Once the drug is released into the target cell, no further transformation is needed, because the entrapment process does not involve any chemical modification of the drug.

Heath et al. have proposed the use of immunoliposomes for the intracellular delivery of compounds that intrinsically do not enter diseased cells. These compounds are cytotoxic if they are transported intracellularly. Methotrexate- γ -aspartate, a good example of this type of compound, has been encapsulated in liposomes composed of phosphatidylcholine, cholesterol, and 4-(*p*-maleimido-phenyl)-butyryl-phosphatidylethanolamine in a molar ratio of 10:10:1. The liposomes were conjugated to either specific (anti-K2Kk IgG2A) or nonspecific MoAbs (antisheep erythrocyte IgG2A). The binding of targeted liposomes was found to be six fold higher to L929 fibroblasts (which express H2Kk protein) than nontargeted liposomes, whereas their binding was comparable in a nonspecific BALB/c 3T6 cell lines. The growth inhibition studies using L929 fibroblasts demonstrated the IC50 of free drug, targeted immunoliposomes, and nontargeted immunoliposomes to be 0.68, 0.066, and 1.2 μ M, respectively (Fig. 4). Hence, the targeted immunoliposomes appeared to be 10 times more effective

than free drug and 18 times more effective than nontargeted immunoliposomes, whereas targeted liposomes actually had the least efficacy in the nonspecific BALB/c 3T6 fibroblasts (63).

Extensive work is being pursued to assess the potential of immunoliposomes for the targeted drug delivery to CD4 positive cells in patients with HIV infection. The HIV infected cells possess CD4, which can be targeted by conjugating anti-Leu3A (CD4) MoAbs onto the surface of drug-loaded liposomes. Preliminary studies showed that immunoliposomes possessing surface-bound anti-Leu3A may be used to target antiviral agents to cells at risk from HIV infection (64). Cell adhesion molecules are glycoproteins expressed on cell surfaces during pathological inflammatory states such as rheumatoid arthritis, atopic dermatitis, and asthma; thus they also provide an opportunity for targeting. An F10.2 antibody against the cell adhesion molecule ICAM-1 was conjugated to liposomes; the immunoliposomes bound to human bronchial epithelial cells in a specific, dose- and time-dependent manner, correlating to the degree of ICAM-1 expression. Immunoliposomes of this type therefore have potential for targeted drug delivery in inflammatory disease states (65).

Heat-sensitive immunoliposomes have also been evaluated for the feasibility of drug delivery (66). These liposomes release the entrapped drug at temperatures above the phase transition temperature of the lipid(s). In vitro cell culture studies based on dipalmitoyl phosphatidylcholine liposomes with entrapped ^3H -uridine have demonstrated enhanced intracellular delivery of drug as compared to that observed with free drug and liposomes without MoAbs. Similarly, selection of appropriate lipids can also allow synthesis of pH-sensitive liposomes. Inclusion of target-cell specific immunogenic moieties in these colloidal particles leads to preparation of pH-sensitive immunoliposomes. Huang and co-workers have used 8:2 molar ratios of dioleoylphosphatidyl ethanolamine and oleic acid to develop pH-sensitive liposomes (67). Arabinofuranosylcytosine (ara-C) and methotrexate were encapsulated in the liposomes that were rendered immunospecific against L-929 cells by homing specific MoAbs. Compared to free drug, drug encapsulated in antibody-free liposomes and pH-insensitive immunoliposomes, the drug-encapsulated pH-sensitive immunoliposomes were found to significantly enhance the cytotoxic activity. Pretreatment of target cells with excess free MoAbs or placebo immunoliposomes was found to block the cytotoxic effect of the drug-loaded pH-sensitive immunoliposomes. In addition, it was shown that the drug release from these specific carrier particles occurs in cell endosomes (67).

Fig. 4 Effect of treatment type on in vitro growth inhibition of (■) specific cell-line, L929 expressing H2Kk protein, and (□) nonspecific cell-line, BALB/c3T6. The targeted and nontargeted liposomes were conjugated with "anti-H2Kk IgG2A" and "anti-sheep erythrocyte IgG2A," respectively. (Adapted in part from Ref. 63.)

Because of the complexities involved with distribution, uptake, and pharmacological effects of targeted drug delivery systems, in vitro results do not always adequately predict the efficacy of a proposed MoAb-targeted system such as an immunoliposome. In fact, there are only a few in vivo studies of immunoliposomes that clearly demonstrate the promise shown by in vitro studies. One encouraging example is a study by Onuma et al. that compared the in vivo efficacy of doxorubicin loaded immunoliposomes against free drug in cows. MoAb c143 against the antigen expressed by bovine leukemia cells was conjugated to liposomes containing doxorubicin. Two groups of antigen-positive cows received four i.v. injections of either 0.4 mg/kg free drug or an equivalent dose of drug via immunoliposomes at an interval of 4 days. Whereas the two animals receiving free drug demonstrated only a slight decrease in their antigen positive cells, the three animals receiving drug-immunoliposomes gradually became free of antigen-positive cells, and 2 of these animals became antigen-negative in 6- and 14-week periods after treatment, respectively (68). In another study, MoAbs against tumor-associated antigens expressed on bovine leukemia cells were conjugated with liposomes containing doxorubicin, and the formulation was administered intravenously to BALB/c nude mice inoculated with BLSC-KU cells on day 0, 3, and 7 after the initiation of treatment. The results were

compared with untreated animals and the animals receiving doxorubicin liposomes conjugated to normal mouse IgG. The doxorubicin liposomes bearing target antigen specific antibodies significantly suppressed the tumor growth. The increase in tumor volume with this treatment, over 10 days after the initiation of therapy, was only 27% as opposed to 166% and 750% in the animals receiving nonspecific therapy and no therapy, respectively (see Fig. 5) (69). Histological screening of the tumors from animals receiving drug-loaded liposomes with specific antibody demonstrated scattered focal necrosis and marked proliferation of macrophages; however, in the untreated animals, active proliferation of tumor cells was observed with little involvement of macrophages (69).

A great deal of attention has been paid in recent years to long-circulating (also called sterically stabilized or “stealth”) liposomes, in which polyethylene glycol (PEG) molecules have been grafted to the surface of the liposomes by covalent attachment of PEG to liposomal phospholipids (specifically phosphatidylethanolamine). These long-circulating liposomes have been shown to avoid the rapid uptake by the reticuloendothelial system (RES), which normally plagues conventional liposomes without PEG; the circulating half-life can be increased by an order of magnitude (70, 71). In fact, the presence of a MoAb on the surface of a conventional immunoliposome may actually increase the uptake by the RES system (72), suggesting that modification to insure long-circulation may be especially important for immunoliposomes. When designing PEG-modified immunoliposomes, the composition must be optimized for both antigen binding and extended circulating lifetimes. Antigen recognition by the liposomal antibody can be sterically hindered by the presence of the PEG. This can be overcome by either reducing the polymer size to 2000, or by moving the antibody out to the terminus of the PEG rather than the liposome surface (72).

Despite the extensive *in vitro* and *in vivo* research on immunoliposomes, these MoAb targeted systems have apparently not yet reached clinical trials. This may be because of a variety of factors, including the difficulty of clearly demonstrating efficacy in suitable animal models, and the obstacles associated with scaleup and manufacture of system as complex as a sterically stabilized MoAb-targeted liposome. Other potential problems of immunoliposomes are that they may not adequately penetrate the vasculature of solid tumors; they may not adequately release the loaded drug into the target cells; and they may demonstrate immunogenicity (73). Use of humanized antibodies may alleviate the latter effect to some extent. Recently, sterically stabilized liposomes

conjugated to Fab' fragments of a humanized anti-HER2 MoAb (similar to Herceptin) were studied *in vitro* using confocal microscopy techniques. The immunoliposomes bound selectively and were internalized by HER2-over-expressing breast cancer cells, reaching 8000–23,000 vesicles/cell at saturating liposome concentrations, which was at least two orders of magnitude greater than cells with low HER2 expression (74). These immunoliposomes, containing doxorubicin and optimized with respect to Fab'/lipid/PEG composition for intracellular tumor delivery, were subsequently examined in an *in vivo* human xenograft breast cancer model; they demonstrated significantly increased antitumor efficacy compared to free doxorubicin or non targeted doxorubicin liposomes, and less systemic toxicity than free doxorubicin (75). The studies demonstrate the importance of optimizing a delivery system with respect to binding to the target epitope as well as uptake and/or release of available drug at the target site. Such considerations are necessary before successful demonstration of efficacy of immunoliposomes in the clinic. An ideal immunoliposome system should allow efficient encapsulation of intended compound so as to protect its degradation prior to and during endothelial transfer, and hence minimize inherent toxicity; it should also allow controlled release of drug

Fig. 5 Effect of treatment type on the increase in tumor volume in mice inoculated with BLSC-KU cells. The animals in treatment groups received *i.v.* doses of doxorubicin via tumor-specific or nonspecific liposomes on day 0, 3, and 7 after the initiation of treatment. The tumor-specific and nonspecific liposomes were conjugated with MoAbs against leukemia cells and normal mouse IgG, respectively. (Adapted in part from Ref. 69.)

in the extravascular compartment of target tissue. In this regard, it should be noted that the delivery systems based on particulate carriers may allow reversal of tumor cell drug resistance (Fig. 6) (76). Nevertheless, immunoliposomes fall short of meeting the above ideal criteria and much work remains to be done before they are clinically useful.

A related approach for lipophilic drugs is MoAb targeted emulsions. For example, a lung-targeted MoAb 34A was conjugated to the surface of a long-circulating emulsion composed of castor oil, phosphatidylcholine, and pegylated phosphatidylethanolamine. Upon intravenous injection into mice, 30% of the injected emulsion dose became preferentially associated with lung tissue within 30 min (77). A similar long-circulating emulsion conjugated to an anti-B-cell lymphoma MoAb LL2 was found to bind *in vitro* to three different Burkitt's lymphoma cell lines, and thus shows potential for delivery of anticancer drugs to B-cell malignancies (78).

Immunomicrospheres

In view of the availability of a wide variety of biocompatible and biodegradable polymers, and the ease of preparation of stable microparticles with predictable physicochemical characteristics, antibodies have been conjugated to polymeric microparticles for controlling their *in vivo* deposition.

Although a few *in vitro* studies have demonstrated promising results with immunomicrospheres (79, 80), limited information has been published on the *in vivo* efficacy of immunomicrospheres for drug delivery. In one case, following promising *in vitro* results, an *in vivo* study was conducted in mice bearing human tumor xenografts, using ^{14}C -polyhexylcyanoacrylate nanoparticles with adsorbed anti-osteogenic sarcoma MoAbs 971T/36. However, the particles were found to deposit predominantly in liver and spleen, and hence the study failed to demonstrate any appreciable improvements in drug delivery due to the immunocarrier (81). Lack of optimal particle size and/or tumor tissue permeability, lack of expression of sufficient Fab portions on the surface of particles, particle opsonization leading to a secondary non-interactive coating, distribution of specific antigens in the liver, and competitive displacement of the adsorbed MoAbs by serum components were suggested as possible reasons for this undesirable *in vivo* distribution of the immunoparticles. Another study has evaluated the *in vivo* drug delivery potential of albumin immunomicrospheres in mice (80). The microspheres bearing Lewis lung carcinoma MoAbs demonstrated slightly higher localization in lung carcinoma at 24 h after its administration.

Fig. 6 A plot showing 50% inhibitory drug concentration *in vitro*, in normal and drug-resistant lines, following treatments with vinblastine solution (□), or vinblastine encapsulated in liposomes (■). The data suggest the possibility of the reversal of drug resistance by using carrier systems like liposomes. (Adapted in part from Ref. 76.)

REGULATORY CONCERNS

While a regulatory agency's prime concern remains the safety and efficacy of a new product in its proposed use, the technological issues concerning the manufacture of monoclonal-based therapeutics are not ignored. Indeed, because antibody-based systems involve specific immune reactions for their response, and they are comprised of components derived from biological origin, it is obvious that the proposed regulatory guidelines for the clinical use of these products are likely to be extremely strict. The technology for the development of antibodies and antibody-based delivery systems is relatively new and has been continuously expanding over the last several years. More and more practical changes in manufacturing process of these systems can therefore be expected over the next several years. Although most products are expected to be handled on a case-by-case basis, the following general guidelines should apply to all antibody-based systems: exhaustive characterization of the origin of cell lines, characterization of production procedures, product purification and characterization, quality control, and validation of processes involved during production and testings. For example, successful approval and use of a MoAb product will mandate declaration of the source, name and characteristics of the parent myeloma cell lines, and all pertinent details regarding the animal

species used for hybridization. The rationale for selecting a particular cell line along with criterion for its acceptance, the genotype and husbandry of animals used for in vivo production, and steps taken to control contamination is expected to play a critical role. Once the product is made, extensive purification to reduce the level of contamination (using techniques like affinity, size exclusion or ion-exchange chromatography and/or ultracentrifugation) is likely to increase the probability of its approval. Measures would need to be undertaken to insure that the product does not contain any biological contaminant transferred from the original malignant hybridoma cell lines.

Once a bulk lot is in hand, its characterization for immunoglobulin and subimmunoglobulin class, and testings for potential aggregation, denaturation, fragmentation of immunoglobulin and immunologic specificity would be required. If a MoAb fragment is used, its degree of homogeneity would need to be confirmed. Finally, information on the sterility and polynucleotide contamination of the lot is likely to be required. It would be expected that the process validation allows rejection of lots with viral or nucleic acid contaminants. Additional tests may include determination of the product stability with respect to fragmentation, aggregation, and loss of potency. The preclinical toxicity testing with the final product would be required in at least one species bearing relevant antigen. Following the identification of an appropriate animal model, GLP-compliant pharmacokinetic evaluations involving in vivo distribution, metabolism and excretion, would be desired.

As mentioned earlier, in most instances the antigens are preferentially associated with the target site rather than specifically present there, i.e., small amounts of the same antigens are present in one or more nontarget organs. Because the probability of unacceptable levels of this cross-reactivity is reasonably high, regulatory guidelines recommend screening for cross-reactivity. For in vitro screening, blood cells, cell culture lines, fluorescent antibody tests, radioaudiography, and/or similar other techniques would be useful. If possible, tissues from unrelated human donors could be used to screen phenotypic expressions of potentially cross-reactive tissue antigens. If these tests demonstrate positive cross-reactivity, extensive in vivo testing in animals sharing similar phenomenon would be required to determine its frequency as well as intensity. Alternatively, an isolated perfused human organ system could be used. If these choices are not available, limited clinical testings may be advisable with particular emphasis on the quantitation of the product's biodistribution over a period of time.

It should be realized that the above guidelines, generally meant to assess and regulate the antibody or antibody-component of an overall product, would need to be expanded and/or modified according to the characteristics of the final product. For example, in antibody-based drug delivery systems, the effect of drug and antibody on the potency and biological activity of the final system would need to be assessed.

CONCLUSIONS

Problems and Possible Solutions

Despite the promise of MoAb-directed drug delivery, there are still a multitude of problems that need to be worked out before the technology makes a large impact on therapy. A MoAb is often not as specific in vivo as would be predicted from in vitro studies; i.e., tumor antibodies may bind to normal cells as well as target cells. Despite the fact that antigens associated with tumor tissue have been identified, antigens are rarely specific enough to allow quantitative drug targeting. For example, CA 19-9, BW 494, and DU-PAN-2 have been identified as pancreatic tumor associated antigens. However, MoAb based therapy of pancreatic tumors has not been encouraging (82). In some cases, peak drug concentrations with MoAbs, in tumor tissue, have been found to be only 2–3 times higher than the surrounding normal tissues (83). Current literature suggests that the availability of high affinity MoAbs, which recognize specific antigens without cross-interaction with normal cells, is still scarce. The only exception to this observation is the surface immunoglobulin idiotype expressed by certain B-cell lymphomas (84).

The lack of genetic stability of antigens on tumor cell surfaces is another cause of low density of target antigen on the tumor cell. Antigenic modulation may result in nontumor specific antigen-antibody reaction, thus reversing the efficacy anticipated from the delivery system. Situations of low antigen density may readily saturate the MoAb-antigen binding. Quantitative evaluation of the localization of MoAbs in tumor tissue, at doses $<100\text{ }\mu\text{g}$, have demonstrated a direct correlation between tumor mass and quantity of antibody localized, and at 2–3 days after administration only 8% of the dose could be detected in the tumor. However, the administration of larger doses of MoAbs have been shown to reduce the fraction localized in the tumor, with 1–2 mg doses almost saturating the tumor (83). The presence of circulating tumor-associated antigens is

another factor that may decrease the overall efficacy of MoAb-directed delivery systems and complicate their evaluation. For example, the presence of circulating carcinoembryonic antigen has been shown to complicate the application of MoAbs against this antigen (85). In view of these problems, MoAb-directed delivery systems may ultimately be restricted to those few cases in which there are relatively high densities of known antigens in all cells of the target site.

The heterogeneity of tumor cells is another problem in targeting; i.e., a specific antigen may not be present in sufficient quantities in all cells of the target tissue to allow selection of suitable antibody. For example, it is now appreciated that multiple metastatic proliferation in a given host, and perhaps even in the same organ, can give rise to malignant tumors that contain heterogeneous subpopulation of cells with diverse biological characteristics, such as growth rate, antigenicity or immunogenicity, cell-surface receptors, response to individual and combined chemotherapeutic and immunological agents, invasiveness, and their overall metastatic potential (86). Trubetskoy et al. have proposed a method for MoAb-based drug delivery to target areas with heterogeneous antigens. The proposed method requires sequential administration of a mixture of modified antibodies against different antigens in the target area followed by administration of drug-carrier that recognizes and interacts with accumulated antibodies (Fig. 7) (87). The practical feasibility of this strategy was confirmed following administration of a mixture of biotinylated antibodies to target components followed by administration of biotinylated and avidin bearing liposomes. The binding of biotinylated liposomes via avidin was found to be higher than that achieved with liposomes bearing single antibody (87).

Solid tumors present special problems due to their frequent lack of vasculature; there is generally poor penetration of MoAbs, their fragments, and drug- or toxin-conjugates into solid tumor tissue. Because of the relatively intact microvascular barrier, and hence difficulties in carrier extravasation, the accumulation and uptake of immunoliposomes by solid tumor tissue is also generally low (88). On the other hand, the natural existence of increased transvascular permeability favors the use of MoAb-drug conjugates for the treatment of general lymphomas and leukemias.

The uptake of MoAb-based delivery systems by the reticulo-endothelial system (RES) is another drawback to these systems. It has been suggested that only 0.1–1% of the administered dose of antibody-based systems reaches nonRES sites, with ~8% dose reaching

non RES sites under optimal situations (89). However, a study comparing the *in vivo* tumor localization of anti-CEA MoAbs, and their F(ab')₂ and Fab' fragments, to human colon carcinoma grafts in nude mice has demonstrated greater tumor uptake of F(ab')₂ and Fab' fragments than the intact MoAbs (90), due to the smaller molecular size of the former. Often multiple intravenous injections, over a course of weeks, have been found to be more effective than single injections (91), and continuous infusion is more efficient than bolus regimen (43).

As mentioned earlier, the immunogenicity of "foreign" MoAbs has always been a major factor in the lack of success of MoAb-based therapeutic systems. It has been suggested that use of (Fab')₂ fragments may improve drug delivery without sacrificing the specificity of antigen-MoAb binding because elimination of Fc portion would likely reduce immunogenicity and nonspecific binding to normal cells (92). Humanized antibodies probably hold the greatest promise in decreasing the immune response of MoAb-based therapies. While immunotherapy with these entities is promising and indicates greatly decreased immune responses, little work has been reported on humanized immunoconjugates. These entities may still be immunogenic due to the non-antibody portion of the conjugate. For example, rats injected with an unconjugated murine MoAb failed to elicit an antibody response, whereas rats injected with a MoAb-Vinca alkaloid conjugate mounted a strong antibody response directed against the linker portion of the conjugate (93).

Future Prospects

New applications in the field of antibody-directed drug delivery may be developed by combining the technology with another form of targeting or other means of optimization. For example, in photodynamic therapy a photosensitizing drug (e.g., a porphyrin, chlorin, purpurin, or phthalocyanine) is localized in a tumor, which is then irradiated to effect cell-killing (94). Several reports have described the use of MoAbs to further increase the localization. For example, Sn (IV) chlorin e6 was linked to the oligosaccharide moiety of an antimelanoma MoAb via a dextran carrier. In vitro studies indicated that phototoxicity was relatively specific for cells that exhibited the target antigen (95). Similarly, a chlorin derivative, meso chlorin e₆ mono(*N*-2-aminoethylamide), was linked via a tetrapeptide linker to an antibody directed against ovarian cancer cells. Targeted conjugates were taken up rapidly by cells and detected within the lysosomes, and the conjugate had higher photodynamic effects on ovarian carcinoma cells than nontargeted conjugates (IC₅₀ of 0.38, 290, and 0.34 μ M for MoAb-HPMA-e₆, HPMA-e₆, and free e₆, respectively) (96).

Another recent approach combines MoAb targeting with enzymatic prodrug activation. In this therapeutic method, called antibody-directed prodrug therapy (ADEPT), an enzyme-antibody conjugate is administered and allowed to accumulate in the target site (e.g., tumor). A latent, nontoxic prodrug is then injected, which on contact with the enzyme is converted into the active parent drug and subsequently kills the tumor cells (97). For example, a glutamic acid derivative of benzoic acid mustard was administered to choriocarcinoma-bearing mice, followed by a carboxypeptidase-antibody conjugate that cleaved glutamic acid from the active drug. Tumor contained the highest concentration of targeted enzyme conjugate, and was the only site in which all prodrug reaching the site was activated (98). The ADEPT technique has been tested clinically in colorectal cancer patients using para-*N*-(mono-2-chloroethyl monomethyl)-aminobenzoyl glutamic acid as the prodrug and an antibody conjugate of glutamate hydrolase as the activating enzyme, with temporary regression of disease in two out of five patients (99).

Despite the problems described in earlier sections, MoAbs should hold an important place in drug delivery and therapy in the future. Although the number of therapeutic applications that will eventually lend themselves to this technology may be small, the problems should not be insurmountable for these applications and may yield important advantages over

other therapies. Proper attention to detail must be taken in the choice of antibody, coupling method, drug, route of administration, dose, and other factors in order to design an effective therapy for a particular disease; possible mechanisms of distribution, uptake, metabolism, and pharmacological effect must be properly understood to develop a rationale for a particular MoAb directed therapy. Humanized antibodies hold great promise to alleviate the immune response encountered in past clinical trials using murine derived antibodies. Many of the problems in the scaleup of MoAb manufacture have been solved, primarily because of the rapid growth of diagnostic applications of MoAbs and the coming to market of therapeutic MoAb's. Much work remains to be done, however, in the scaleup of immunoconjugates and complex systems such as immunoliposomes and immunomicrospheres. Nevertheless, it is likely that the next decade will see a number of MoAb-directed therapies reach extended clinical trials and perhaps come to the market.

Molecular and Cellular Approaches to Lead Optimization in Pharmaceutical Development

C. K. Atterwill

M. G. Wing

Huntingdon Life Sciences, Cambridgeshire, United Kingdom

INTRODUCTION

Sensible lead candidate selection for preclinical development and registration should reduce the high rate of drug attrition, the cost of which increases with the distance that the failed drug candidate has proceeded down the research and development pipeline. It is estimated that “adverse” toxicokinetic and safety factors encountered during animal and human exposures in drug development account for approximately 60% of the reasons for termination during development (Fig. 1). Of this 60%, a combination of undesirable animal and human toxic events account for 21% of the total factors involved. Rates of attrition are high, especially during the early regulatory toxicology and clinical phases of testing. (Fig. 2). Not surprisingly, because of the large number of hits identified from primary high-throughput screens, lead candidate optimization has, therefore, emerged as a critical decision-making milestone from both ethical and commercial perspectives. The “models” or strategies for incorporation of a preclinical lead optimization stage are shown in Fig. 3. Essentially, the “old” or, in many cases, current, strategy is to take several lead candidate compounds through early small-scale clinical pharmacological/toxicokinetic/safety studies in vivo before a final selection is made following 1 month toxicology exposures on the lead development drug candidate for clinical exposure. Any later problems with the compound may then facilitate the design of a lead optimization “screen” at an earlier stage for possible follow-up compounds. A more modern and desirable approach would be (and is used in many cases now) to insert a mandatory in vitro ADME-Tox “screen” at the stage before the preliminary in vivo ADME-Tox exposures, which would then produce a “clean” lead development candidate (LDC) for full regulatory testing (Fig. 4). In short, there is a need for early rapid and robust screening assays which that will allow a lead series of compounds to be ranked for desirable or undesirable characteristics.

These preclinical lead optimization technologies (PLOT’S)^[1] must be sufficiently rapid to interface with high-throughput screens without creating a further pipe-

line bottleneck, be predictive of drug failure, and be highly cost-effective (Fig. 4). The assays which constituting the PLOT platform are typically in vitro systems, miniaturized and amenable to automation, thereby achieving the required throughput with minimal compound use, another crucial and limiting factor for facilitating the process of lead optimization (Fig. 5). Industry recognition of the Three Rs (3Rs) of *reduction, refinement, and replacement*,^[2] through the implementation of ethical review processes (ERP), have been partly instrumental in the increasing acceptance and incorporation of alternative in vitro models in early drug development. Additionally, pressure from other bodies such as the UK House of Lords Select Committee on Animal Experimentation, for researchers to pay increasing awareness to the 3Rs will hopefully add to the efforts made across all sectors, public and commercial, to integrate these new technologies into their processes.

PLOT IN PRACTICE

In common with any new paradigm shift, the PLOT strategy must overcome a number of hurdles. Hitherto, pharmaceutical drug discovery project teams have made decisions on compound development based largely on toxicokinetic data derived from short-term in vivo, range-finding compound exposures, which provide very limited evidence for organ-specific toxicity. This former reliance on in vivo data represents a significant obstacle to the PLOT strategy, because decisions on compound selection/rejection based on in vitro PLOT would be made before any animal exposure. Furthermore, as compounds that are selected for drug development following assessment by PLOT will still need to be evaluated in regulatory toxicology studies, it is essential that the PLOT screens are predictive of the corresponding regulatory equivalent, if it exists. The point is well illustrated by the popularity of the high-throughput SOS reporter gene mutagenicity assay, which gives results that correlate well with the regulatory gold-standard Ames assay,^[3] and requires one-tenth of the amount of compound compared with the micro-Ames assay.

Fig. 1 Reasons for termination of research on novel chemical entities (NCEs). Data taken from information on new compounds taken into clinical trials by seven major UK pharmaceutical companies (1964–1985). (View this art in color at www.dekker.com.)

There are many individual reasons for preclinical/clinical drug failure, as listed in Table 1. These include mutagenicity, target organ toxicity, and poor bioavailability, the last being a result of a number of factors including poor absorption across the gastrointestinal tract, rapid clearance, or metabolism. A major factor for preclinical/clinical failure is the lack of suitable, practical, and/or sensitive biomarkers for target organ toxicity from which hazard and risk prediction can be extrapolated cross-species. It is anticipated that the advent of Molec-

ular Toxicology (i.e., toxicogenomics and proteomics—see later sections) will add considerable impetus to the toxicology biomarker area and incorporation into clinical pathology test batteries during drug development. Finally, unless the correct nonrodent species is selected for predicting human safety in regulatory toxicology studies, drug failure or serious adverse drug reactions (ADRs) may not occur until after preclinical development. In vitro PLOT screening can help select the correct nonrodent species very early in development.

PLOT TECHNOLOGIES

The final choice of assays, and the order in which they are performed, will depend on a number of factors, which include lead series number, compound availability (amount), the intended target, and the nature and extent of existing data on the lead series. Ideally, higher-throughput basic or level 1 screens that measure the ADME profile of the compounds should be used to analyze the large lead series, with lower-throughput toxicology assays reserved for a reduced lead series, based on compounds which have negotiated the level 1 filter (Table 2).

Because poor bioavailability represents one of the principal causes of compound failure, absorption and

Percentage of medicines dropped at each stage of development: 1997-2001

Fig. 2 Tabular representation of preclinical and clinical testing phases of drug development at which new compounds have been showed to fail for toxicokinetic and safety reasons. The data show profiles between 1997 and 2001, and also indicate the proportional contribution of safety vs. efficacy testing during drug development. (View this art in color at www.dekker.com.)

Preclinical Lead Optimisation Models

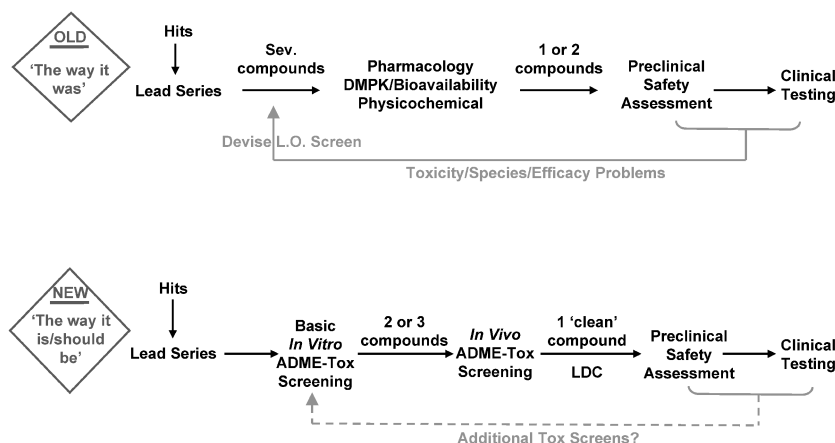

Fig. 3 Diagrammatic representation of Old and New strategies for lead optimization of new pharmaceutical molecules. The top section indicates the Old (and in some cases, current) way in which pharmaceutical companies take Hits to lead development candidate through discovery and early preclinical development testing. Essentially, no high-throughput formal lead optimization exists in this model but is developed for backup compounds by using biomarkers identified during lead compound failure in vivo. The bottom section indicates the New way forward (used now by most major pharmaceutical companies). In this model, a formal in vitro PLOT battery is inserted early in development before preliminary in vivo ADME-Tox screening and subsequent lead development candidate selection. (View this art in color at www.dekker.com.)

metabolism assays feature prominently in lead optimization screens. As oral administration represents the ideal route of drug delivery, models that predict low absorption across the gastrointestinal (GI) tract are commonly em-

ployed. Caco-2 cell assays have been widely used to predict drug uptake across the GI track, and a good correlation between in vitro and clinical data certainly exists for certain drugs (Fig. 6). This assay can also predict compounds that are substrates for the P-gp transporter, which leads to the undesirable efflux of an absorbed drug back into the lumen of the gut, resulting in its excretion. One drawback of the Caco-2 is its relatively low throughput, and so the parallel artificial membrane permeability assay (PAMPA) is increasingly used as a higher-throughput assay for the cost cost-effective assessment of passive drug absorption.^[4] Because these artificial membranes lack the cellular proteins associated with the active transport/efflux, or indeed metabolism, Caco-2 assays or cell lines transfected with specific drug transporters and human P450s may be used as a second and third tier for compounds with high permeability in the PAMPA assay (reviewed in Ref. [5]).

This principle of offering minimal core assays to screen large lead series applies well to the assessment of metabolism, which would be included as a level 1 assay (Table 2). In vitro metabolism assays might initially concentrate on compound stability in the presence of hepatocytes, microsomes, or an S9 extract, but extend to drug interactions on a more restricted series because apparent metabolic stability may be a result of inhibition of P450 function. As CYP3A4 accounts for $\times 40\%$ of the

Optimisation Technologies (PLOT) in Drug Discovery and Development

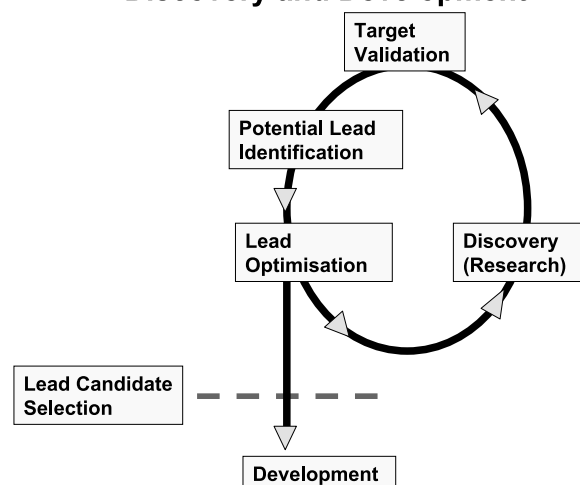

Fig. 4 The R&D ‘pipeline’ in modern drug development. (View this art in color at www.dekker.com.)

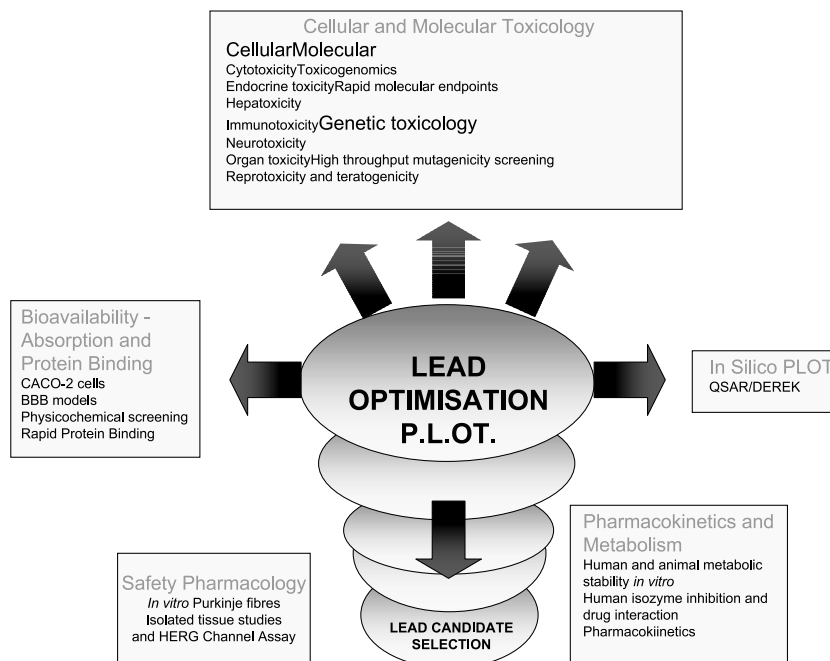

Fig. 5 Platforms comprising the preclinical lead optimization technology (PLOT) “filters” in the selection of lead development candidate molecules in drug development. (View this art in color at www.dekker.com.)

total cytochrome P450 in man, and is responsible for the metabolism of $\times 50\%$ of clinically used drugs, it makes sense to screen the inhibition or induction of this enzyme. Modulation of CYP3A4 activity is traditionally investigated by measuring enzyme function, i.e., testosterone metabolism or looking at enzyme levels by polymerase chain reaction (PCR) or Western blot, which may not be a cost-effective approach for large series lead optimization. However, recent advances in our understanding of the molecular basis for CYP3A4 induction have

identified the PXR (pregnane X receptor) as being important in drug-induced expression of this and other CYPs. Consequently, PXR reporter gene assays are being used to screen drugs with the potential to induce CYP3A4 (see, e.g., Ref. [6]), with positive results justifying a more intensive investigation. Other enzymes worth consideration are those where the existence of functional polymorphisms could limit the geographical market for a drug.

Mutagenicity testing is normally performed fairly late in compound development; however, as regulatory genetic toxicology testing in our laboratories consistently produces 20–25% *in vitro* positive results each year—which at best results in significant delays while further investigations are conducted or, at worst results, in compound failure—a faster and earlier screen is required. As described above, there now exist high-throughput reporter gene assays for mutagenicity, such as the SOS/umu assay. This has low compound requirements, and is suitable for inclusion in the PLOT platform. The basis for this microassay, originally developed by Oda et al.^[7] and adapted by Reifferscheid et al.,^[8] is that *Salmonella typhimurium*, carrying the SOS DNA repair gene fused to a reporter, respond to DNA damage by transcribing the fusion gene whose expression is correlated with the extent of DNA damage. A mammalian reporter assay, in which the human DNA repair

Table 1 Reasons for early preclinical/clinical failure

Insoluble	}	Poor bioavailability
Poorly G1 absorbed		
Fast cleared and/or metabolized		
Mutagenic/teratogenic		
Toxicity is pharmacologically/ target organ-related		
Cytotoxic/hepatotoxic		
Wrong choice of tox species to predict human safety		
Poor detection sensitivity of safety test system		
Drug–drug interactions via P450 isozyme competition/ induction/inhibition		

Table 2 Higher-throughput basic screens (level 1) and lower-throughput toxicology assays (level 2)

Level 1 assays

Physiochemical Screening—experimental and computational solubility, log *P*, log *D*, and *pK_a*

Rapid protein binding

Mutagenicity—bacterial reporter gene assay (SOS repair system) and DEREK (in Silico)

Cytotoxicity—MTT or neutral red uptake assay on mammalian cells

In vitro metabolism I—parent compound loss following hepatocyte or microsomal incubation

In vitro Metabolism II—drug–drug interactions, P450 characterization and P450 induction

Absorption I PAMPA

Absorption II—Caco-2 model

Absorption III—cell lines transfected with drug transporters

Level 2 assays

Immunotoxicity—inhibition of lymphocyte transformation and histamine release

Reprotoxicity and Teratogenicity—micromass and whole-embryo assays/stem cell assay

Hepatotoxicity—enzyme release and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay on fresh or cryopreserved (human) hepatocytes

Endocrine disruption—yeast and mammalian reporter gene assay (oestrogenicity and androgenicity)

Neurotoxicity—brain spheroids (central nervous system (CNS)) and dorsal root ganglia (DRG) neurite outgrowth (peripheral nervous system (PNS)) assay

Cardiotoxicity—HERG patch clamp and/or HERG ligand assay

genes are fused with a reporter, is currently unavailable and eagerly awaited.

IN SILICO PLOT

Because compound availability will typically be limiting in terms of compound use, there is clearly an advantage in being able to perform computational physiochemical predictions of compound partition coefficients, isoelectric points, and solubility, based on structure. The computational prediction of drug bioavailability has been pioneered by Lipinski's "Rule of Five," which is based on compound molecular size, hydrogen bonding capacity, and lipophilicity.^[9] Increasingly sophisticated packages are being developed to analyze compound structure–activity relationships (SAR), i.e., ascribing toxicity to certain structures or substructural features. Compounds containing aromatic amines will be flagged as potential mutagens, or the existence of protein binding groups will be used to identify potential sensitizers.

PLOT AND TARGET ORGAN TOXICITY

The aforementioned basic ADME assays logically precede compound investigation in the lower-throughput, organ-specific toxicology assays, typically selected on the basis of single exposures in vivo, which may incorporate efficacy and toxicokinetic endpoints, subject to compound availability. The identity of organ-specific toxicity in vivo may stimulate the synthesis of a further lead series around the compound exhibiting the best ADME profile in the level 1 screens (Table 2). Because the liver represents a primary target organ for toxicity, level 2 screening for hepatotoxicity (e.g., using hepatocytes) may be selected by default, involving measuring enzyme release or metabolic activity by using primary hepatocytes in vitro. Although access to fresh human hepatocytes is always likely to remain problematic, it is anticipated that technical improvements will overcome current shortcomings in the quality of cryopreserved cells.

The increasing acceptance of in vitro assays by the regulatory bodies may also influence the choice of organ cultures. The ICH S7B Safety Pharmacology guideline,^[10] for instance, recommends cardiac toxicity to be evaluated on all new pharmaceuticals by investigating their potential to cause a delayed ventricular response in vitro in isolated cardiac Purkinje fibers and/or human cell lines transfected with HERG channels, alongside measurements in conscious animals (Fig. 7).

The loci of drug action in causing toxicity and ECG QT interval prolongation via block of HERG channels and leading to Torsades Des Pointes is shown, together with examples of known molecules producing such effects. (View this art in color at www.dekker.com.)

An alternative rationale for the selection of level 2 assays can be based around the intended target tissue; thus, drugs designed to target the central nervous system or immune system would warrant the use of level 2 assays to screen for, e.g., neurotoxicity or immunotoxicity, respectively. A second area where immunotoxicity screening would be especially important are clinical indications involving immunocompromized patients, where a functional assessment of the immune system is required as part of the preclinical development.^[11] These would include HIV and transplantation patients, who would be especially vulnerable to compounds with even minimal immunotoxic side effects. The in vitro assessment of reprotoxicity and teratogenicity have typically employed the low-throughput mouse whole-embryo, micromass, or xenopus assay. However, recent progress has been made in this area with the validation of an in vitro embryo-toxicity assay employing a stem cell line,^[12] which is amenable to higher throughput and represents a genuine level 2 in vitro assay (Table 2).

In summary, level 2 in vitro assays are employed to select, from lead compounds associated with the least target-organ toxicity, by using an appropriate in vitro screen. This process of in vitro screening, alternated with

in vivo exposure, may even extend beyond lead candidate selection in situations where lead candidate failure necessitates a lead follow-up series to be synthesized and screened in vitro by using PLOT platform (Fig. 3).

IRRITANCY, CORROSIVITY, SENSITIZATION, AND PHOTOTOXICITY

This is an area of significant advancement for industrial chemical notification and registration where several in vitro techniques have been legislated in favor of animal tests in certain scenarios or take their place in tier-testing strategies. The European Medicines Evaluation Agency (EMA) has also taken a positive stand on the replacement of animal studies by in vitro methods.

There is not a widespread use of primary in vitro screening assays by pharmaceutical companies to detect potential skin and eye toxicity in the lead optimization process. However, as some of these assays will be required as part of the worker safety/transportation/pre-clinical regulatory package, there are instances when these tests should perhaps be considered as part of the

selection process. In vitro assays exist that may be suitable for the assessment of skin and eye toxicity, some of which have received recent acceptance of by the EU regulatory authorities under the 27th Adaptation to Technical Progress following their successful validation by ECVAM. Accepted tests currently include measurement of skin corrosivity (i.e., EpiDerm™ or rat skin transcutaneous electrical resistance) and phototoxicity (3T3 cells). Other assays undergoing validation may already be acceptable to the regulatory authorities on a case by case basis (i.e., eye irritancy); however, in the absence of a positive result, an animal test would still be required. In addition to corrosivity and phototoxicity, it is anticipated that in vitro assays will ultimately allow irritancy and sensitization to be predicted.

In addition, when considering pharmaceutical compounds requiring intravenous, ocular or topical routes of administration as a strategic part of their development plan, then the same consideration for early in vitro screening should be made. In fact, if the final development plan for a particular therapeutic class indeed required such routes, then the lead optimization process (or some later preclinical selection step) could screen for these eventualities at an early stage.

MOLECULAR TOXICOLOGY AND PLOT

It has been stated that there are no toxicologically relevant outcomes in vitro or in vivo, with the possible

exception of rapid necrosis, that do not require differential gene expression arising through mRNA transcription or stabilization.^[13] These “stress” gene responses constitute an evolutionary developmental means by which an organism can protect itself from a hostile external environment (Fig. 8), and activate survival or “self-destruct” processes through apoptosis. Thus, the use of microarray technology [gene expression microarrays (GEMs or ToxCChips)] to establish gene expression “fingerprints” or expression patterns following compound exposure, and thus to develop screening systems for in vitro lead optimization processes, has become attractive to preclinical scientists interested in drug safety. For more in-depth information on the type and extent of stress genes and their expression patterns, the reader is referred to Refs. [13,14]. In addition to the measurement of gene expression, it is now possible to perform high-throughput proteomic profiling on cell extracts or body fluids by using platforms such as Ciphergen’s protein chips or specific protein profiles using antibody arrays. The analysis of protein vs. RNA may be preferable where the correlation between gene expression and protein is poor, where there is a low dynamic range for RNA upregulation, or in situations where protein function is post-translationally regulated (e.g., by phosphorylation) for instance. Furthermore, because biomarkers may be readily found in blood and urine, they provide a noninvasive source of starting material for proteomic analysis. The potential application of “omics” technologies to the modern research and

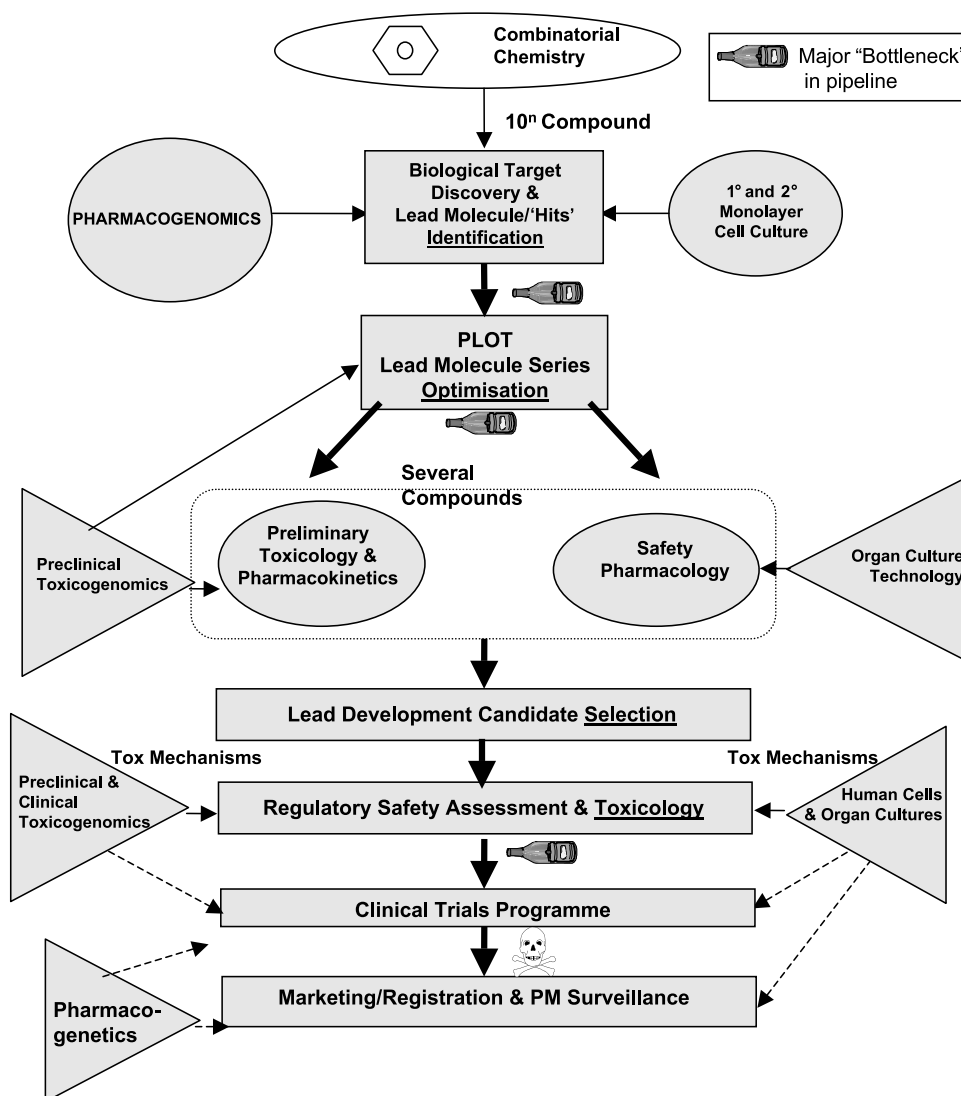

Fig. 9 Diagrammatic representation of the different stages in drug discovery and development showing where pharmacogenomics, toxicogenomics, and pharmacogenetics can be applied to a more “sophisticated” paradigm in tandem with the use of various cell culture technologies. The different potential bottlenecks in the process are also shown. (View this art in color at www.dekker.com.)

development process for new drug discovery and pre-clinical/clinical development is depicted in Fig. 9. Ultimately, this process will identify a lead development candidate molecule (lead candidate selection), by virtue of its failure to switch on “patterns” of stress genes or toxicity genes. The type of logistics potentially involved in preclinical toxicogenomics is depicted in Fig. 10, where lead candidates are tested in organotypic cultures or in vivo to look for evidence of toxicity using molecular endpoints in conjunction with traditional methodologies. Comparison with existing in vivo and emerging in vitro databases will increasingly allow the prediction of com-

pound toxicity, allowing further rounds of lead optimization to be performed in vitro to find cleaner drugs. This toxicological PLOT screen would, then, allow lead development candidate molecule selection by employing higher-throughput molecular technologies.

CELLULAR AND MOLECULAR “TOOLS” IN REGULATORY TOXICOLOGY

Following lead candidate selection and progression to the regulatory safety assessment program, toxicogenomics

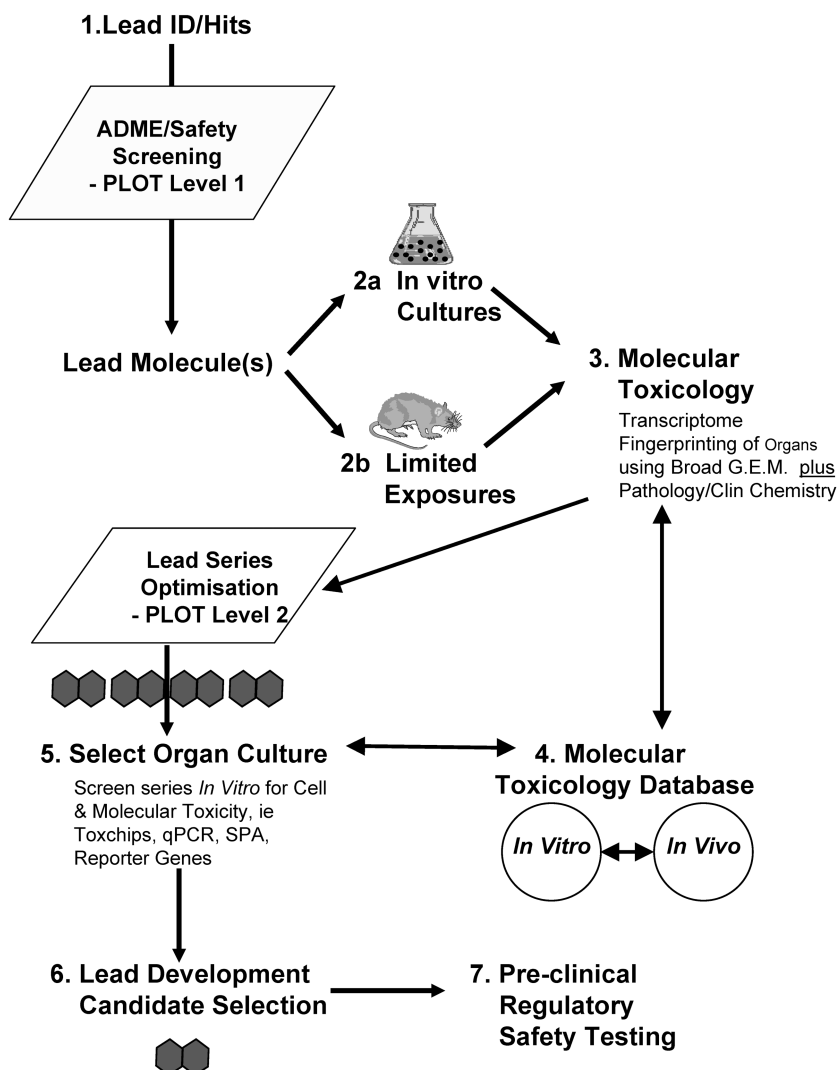

Fig. 10 A potential strategy for the selection of a lead development candidate molecule using toxicogenomic technology. Following lead optimization of a number of molecules using basic PLOT/ADMET screening (PLOT Level 1), one or several promising candidates might be administered (at high exposure levels) to a single animal whereby the organ pathology/biochemistry would be compared with tissue stress gene responses using gene chip/protein chip technology. Using this information, coupled with “knowledge” of toxicity-related stress gene/protein fingerprints from established databases, a cellular/in vitro screening system could be set up (PLOT Level 2) based on the principal gene/protein responders to screen out toxic molecules from further lead molecular series. The lead development candidate for further in vivo testing and full preclinical safety evaluation would then be selected based on a composite set of ADMET/PLOT and cellular target-organ toxicity data. (View this art in color at www.dekker.com.)

can be once more used (Fig. 9), to complete various aspects of the preclinical and clinical hazard and risk assessment process: this involves applying the same basic technologies as described above. However, there may be differences in interpretation of data, and more emphasis may be placed on the use of cells (in vitro or ex vivo) from nonrodent (e.g., dog or primate) species and humans. This would help to facilitate risk assessment as one moves from animal to human safety and Phase I clinical trials, as

well as the administrative and regulatory processes associated with new drug development.

Single nucleotide polymorphisms (SNPs) are single nucleotide differences present throughout the genome, which differ between unrelated individuals. Where they result in changes to the coding region of genes, the cSNPs may affect protein efficiency or specificity, which may ultimately result in adverse drug reactions (ADRs), as in the case of some of the P450 polymorphisms. This

problem is well illustrated by certain CYP2C9 polymorphisms and warfarin-associated haemorrhaging. The availability of SNP databases will increasingly permit pharmacogenetics to reduce the uncertainty in predicting an individual's response to new medicines by SNP profiling. Pharmacotoxicogenetic analysis of such SNPs will add information and enable a better selection to be made of volunteers or patients, and will ensure optimal safety/efficacy assessment for drug-tailored trials and therapies with the registered drug (Fig. 9). The importance of pharmacotoxicogenetics has not been lost on the regulatory bodies, and there is already an ongoing dialogue between the European Medicines Evaluation Agency and the pharmaceutical industry, to discuss the implications of this technology for the design of clinical trials.^[15]

HURDLES AND THE WAY FORWARD

It is of paramount importance to bear in mind that applying preclinical and molecular clinical technologies to regulatory drug development toxicology and human risk assessment, as described above, may preclude some pharmaceutical organizations from take-up on this strategy until the regulatory perspective is more clearly defined. Toxicology bioinformatics databases (containing gene expression data) are evolving that also contain conventional histopathology, hematology, and clinical chemistry data, in attempts to link these new molecular technologies with those biomarkers already established and familiar to regulatory toxicologists. Commercial organizations, (such as Memorec and Genlogic Inc.), as well as academic and governmental regulatory agencies, are now mindful of this need and are using both in vivo and in vitro exposure data to this end for both pharmaceuticals and industrial chemicals. In particular, human and rat hepatocytes have recently been extensively used for such validation studies and toxicogenomic data incorporated into databases alongside in vivo animal exposure data.^[16,17] In addition, (and from a pragmatic perspective), there may be the need to redefine the formal risk-assessment process (from a quantitative standpoint) in progressing from animal to first human exposure in terms of these new and relatively unknown "sets" of sensitive molecular biomarkers which may result in different no-observed effect levels/lowest observed effect levels, from the classical toxicopathological endpoints, and thus in potentially different levels of safety margin factoring in risk assessment.

In this paper, we have attempted to describe how basic ADME level 1 and organ toxicology level 2 PLOT platform assays can interface with high-throughput screens to help make decisions on selection of a lead development

candidate. It is envisaged that histopathology will increasingly be used in parallel with more-sensitive open gene array or proteomic analysis of tissues following in vivo exposures, as a means of identifying new "batteries" of toxicopathological biomarkers for preclinical toxicology and human safety assessment. It is not possible to pioneer new destinations in drug development and safety assessment until the journey has been undertaken. En route, much information has been collected and "casualties" have been inflicted, hence the need for comprehensive databases of molecular toxicological informatics to be established in different species vs. humans.

It is clear then that we are now entering a new era of both lead optimization technology and drug development. As we move from "old" to the "new" models for lead optimization of pharmaceutical molecules, (Fig. 3), harmonized preclinical strategies across the pharmaceutical industry are gradually being incorporated into research programs, mindful always of the need to apply the Three 3Rs principles of Russell and Burch^[12] to safety testing.

MOISTURE IN PHARMACEUTICAL PRODUCTS

R. Gary Hollenbeck

University of Maryland School of Pharmacy, Baltimore, Maryland, U.S.A.

INTRODUCTION

The earth contains 75% water (1), some of it in pharmaceutical products. With regard to solid dosage forms, pharmaceutical scientists have struggled for years to answer questions on how much is there, in what form is it, and if, when, and how might it influence a product or manufacturing process.

The term moisture, usually defined as wetness conferred by an unidentified liquid (2), is assumed here to be due to water. Thus, the scope of this article is the characterization of and consequences due to relatively small amounts of water associated with solids of pharmaceutical interest. Chemical stability, crystal structure, powder flow, compaction, lubricity, dissolution rate, and polymer film permeability are some properties of pharmaceutical interest that have been demonstrated to be influenced by the presence of moisture. Wet granulation, extrusion, spheronization, tray drying, freeze drying, spray drying, fluid-bed drying, tableting, and aqueous film coating are some unit operations that obviously depend on the amount and state of water present.

Moisture can and does influence the properties of individual active ingredients and excipients, and it is essential, as a first step, to characterize the effect of moisture on these individual components. Indeed, most of this article examines the sorption behavior of specific chemicals. However, the behavior of a pharmaceutical formulation is a complicated function of the individual component attributes. The following is an example of heterogeneous moisture distribution: A powder blend containing 2% moisture has a 10% content of an hydrophilic binder. If one assumes that all the moisture is associated with the binder, the moisture content of the binder itself would be 20%. Photomicrographic evidence demonstrates dramatically how the presence of a disintegrant, for example, can dramatically alter the environment in which a moisture-sensitive drug may exist at a particular relative humidity (3). Even though at least one model has been developed that allows the prediction of component moisture contents in a blend (4), the distribution of water in complicated formulations is largely uncharted territory.

Historical Perspective

In the area of moisture in pharmaceutical products, it is possible to identify three stages in the scientific and regulatory history. The first stage dealt more or less exclusively with the amount of water present in pharmaceuticals, most of which were products of natural origin, with regard to issues of potency and commerce.

In the second stage, there was a realization that water could affect the chemical and physical properties of drugs and dosage forms. The fact that water might exist in different states was exemplified by partitioning the water into "bound" or "free" moisture. The implication was that the free, or solvent-like, moisture was responsible for most stability and production problems (5).

The third stage came with the realization that even small amounts of "bound" moisture could have a dramatic impact on properties and processes of pharmaceutical interest. In the evolution of this scientific pursuit, it is now evident that the state of moisture is as important as the amount present. Although sophisticated thermodynamic characterization of adsorbates has been the subject of research since the pioneering work of Gibbs (6), this stage has been enhanced by the ability to examine behavior at the molecular level by using powerful new analytical tools.

Over the years, only few studies linked a thorough characterization of moisture with physical and chemical stability and production problems. Recent interest indicates that the subject is still important, there are still questions to be answered, and the gap between thermodynamic characterization and technological application will continue to narrow.

Compendial Standards

The methods for moisture determination in USP 24/NF 19 (7) are at best, classical, addressing only the determination of moisture content (8). The specifications for most official articles are arbitrary and may be excessively restrictive or broad. They are not supported by the type of data referred to previously that relate moisture content to the stability or performance of the article.

A USP Advisory Panel on Moisture Specifications initiated a revision process (9) with the inclusion of background material in the general chapter <1241> “Water-Solid Interactions in Pharmaceutical Systems.” However, this occurred over 10 years ago and it has not been followed by the inclusion of standard analytical tests that can be used to characterize the state of water.

The USP offers two methods for the determination of moisture content in solids: titrimetry (Karl Fisher titration) and gravimetry (e.g., thermal gravimetric analysis). Applications, advantages, and disadvantages of these methods are addressed later. Most articles listed in the official compendia contain specifications on “water” or “loss on Drying (LOD).” For chemicals, the gravimetric method is the same as the physical test in the general chapter <731> “Loss on Drying” (8). As volatile components other than water may be present, loss on drying is not a de facto moisture content determination. Inclusion of a “water” specification is an indication that the only volatile component present is water.

The nature of moisture content determinations is perhaps best exemplified by the fact that the *Handbook of Pharmaceutical Excipients* (10) lists 31 separate versions of laboratory tests to determine moisture content and one to determine equilibrium moisture content. These methods were used to assess the moisture content in the compilation of 148 monographs (10), many of which do not deal with solids.

BACKGROUND

Conventions, Definitions, and Terminology

The subjects of moisture and solids have not been distinguished by clear definitions and consistent usage. Table 1 clearly defines terms that are often misused.

Several conventions will be followed in this article. Moisture contents are expressed on a dry weight basis. When necessary, the subscript 1 is used for water, and the subscript 2 for the other component in the adsorbent; in the absence of a subscript, the property is to be attributed to water. Results of many routine tests conducted in my laboratory have been included here. Although the specific equipment used and all the experimental details are not provided, an effort has been made to include information that can substantially influence the results of the test (e.g., heating rate in thermal gravimetric analysis). These data should be taken as being representative of the substance tested and not necessarily as the results to be expected for a given lot of the substance examined with different instrumentation under different experimental conditions.

The sorption isotherm is the most widely used expression to quantify a substance's affinity for water. It is, as the term implies, a relationship at a constant temperature.

$$n = f(x) \quad (1)$$

where n , the number of moles of water sorbed, is a function of x , the partial pressure of water in the atmosphere at that temperature. The correspondence of n to moisture content and x to relative humidity, as defined in the Table 1, suggests that this functional relationship may be stated in numerous ways. Often, the graphical presentation of sorption isotherms is a plot of the dependent variable moisture content versus relative humidity, with both expressed on a percentage basis.

Idealized moisture isotherms are presented in this article for substances that sorb moisture in discrete stages (e.g., crystalline materials capable of forming a hydrates) and for substances that do not interact with water in discrete stages (11). These idealized isotherms form a basis for the discussion of deviations and unexpected effects of moisture sorption that can influence the physical or chemical properties of the solid.

Figure 1 is a sorption isotherm constructed for a hypothetical solid with a molecular weight of 180, which is capable of forming a monohydrate. In this case, the solubility of the substance in water is assumed to be 50 wt% and the critical humidity for the transition from anhydrous to monohydrate is assumed to be 60% RH. It is also assumed that a solution of the solid in water behaves ideally.

The stepwise character demonstrated in this profile is characteristic of a substance capable of forming a hydrate. At humidities below 60% RH, the moisture content of the solid remains virtually unchanged. When the activity of water reaches a critical relative humidity of 60%, water is sorbed by the solid as the anhydrous form converts to the monohydrate. For this example, the moisture content associated with the complete transition to the monohydrate is 10% (e.g., 1 mole of water = 18 g; 1 mole of the substance = 180 g).

Further increase of humidity has no appreciable effect on moisture content until a water activity is reached equal to that associated with a saturated solution of the substance in water at the temperature of the analysis. The relative humidity associated with this activity will be referred to as RH_s . In this case, $RH_s = 91\%$ relative humidity, as the solubility of 50 wt% is $x_2 = 0.09$. On a mole fraction basis, and, assuming ideal solution behavior, $x_1 = 1 - x_2 = P_1/P_1^0$. In this hypothetical case, the moisture content of the saturated solution when all the solid is dissolved is 100%; therefore, at 91% RH the monohydrate sorbs water from the atmosphere until dissolution is complete. The fact that constant humidity is produced by a saturated solution of a

Table 1 Definitions

Term	Symbol(s)	Definition
Sorption		The spontaneous acquisition of a component (water in this case) from the atmosphere by a system.
Adsorption		Sorption confined to the surface of the solid. The amount of water adsorbed is directly proportional to the surface area available.
Absorption		Sorption characterized by penetration of the sorbed component into the bulk structure of the solid. The amount of water absorbed does not depend on surface area.
Desorption		The spontaneous loss of the sorbed component (water) to the atmosphere.
Sorbent		The substance or system responsible for sorption.
Adsorbent		Ostensibly the substance responsible for adsorption. The term “absorbent” is not in common usage. Adsorbent is used without discriminating between adsorption or absorption.
Adsorbate		The substance being adsorbed (water in this case).
Moisture content	MC, W	The total amount of water present with the adsorbent.
Dry weight basis	W_D	An expression of moisture content related to the weight of dry solid.
	$\%MC_D$	$W_D = \text{wt. water/wt. of dry solid}$ Amount of moisture present with 100 g of dry solid.
		$\%MC_D = 100W_D$
Wet weight basis	W_W	An expression of moisture content referring to the total weight of the sample.
	$\%MC_W$	$W_W = \text{wt. water/wt. of sample}$ Amount of moisture present in 100 g of sample.
		$\%MC_W = 100W_W$
Equilibrium moisture content	EMC, $\%EMC$, $W_{D,eq}$, $W_{W,eq}$	The moisture content (sometimes expressed on a percentage basis) at equilibrium under specified conditions of temperature, pressure, and vapor composition.
Partial pressure of water in the atmosphere	P/P_0	The vapor pressure of water in the atmosphere (P) expressed as a fraction of the saturation vapor pressure of pure liquid water (P_0) at the same temperature.

(Continued)

Table 1 Definitions (*Continued*)

Term	Symbol(s)	Definition
	x	As the behavior of water vapor is generally assumed to be ideal (fugacity = pressure), x is the activity of water.
Relative humidity	%RH, $100P/P_o$, $100x$	The vapor pressure of water in the atmosphere (P) usually expressed as a percentage of the saturation vapor pressure of pure liquid water (P_o) at the same temperature.
Term	Symbol(s)	Definition
Bound moisture		Water associated with a solid exhibiting a vapor pressure less than P .
Free moisture, unbound moisture		Water present in a solid exhibiting a vapor pressure greater than P . This water is sometimes referred to as "freezable" water.
Hygroscopicity		A term synonymous with sorption, implying an acquired amount or state of water sufficient to affect the physical or chemical properties of the substance.
Water of hydration		Water present in regular positions within a crystal lattice (3). (There is a specific stoichiometry with the other molecule.)
Efflorescence		Spontaneous loss of water of hydration (not thermally induced).
Deliquescence		Sorption sufficient to produce dissolution of the substance.
Monolayer capacity	V_m	Volume of water (STP) adsorbed at STP when the surface is covered.
	Y_m	Amount of water adsorbed when the surface is covered.

substance has been used as a basis for establishing controlled-humidity chambers.

At relative humidities above 91%, the colligative behavior of the solution results in absorption of water until the solution is in equilibrium with water vapor in the atmosphere. In Fig. 1, this region has been constructed based on Raoult's law.

Although some specific examples are given, several aspects of the sorption of water by crystalline substances deserve attention at this point. First, it is important to recognize that the large quantity of water that associates with these systems actually obscures small changes in moisture content that occur between hydrate transitions. It has been stated that lactose monohydrate, for example, "contains 5% water of crystallization and approximately

0.1% adsorbed water" (10), indicating that adsorption takes place on the hydrate.

Furthermore, this sorption isotherm is a thermodynamic relationship. Although it represents the equilibrium position, it does not provide any information about the rate at which the transitions take place. For example, the desiccant calcium sulfate goes through two stages of hydration, as shown in Eq. (2).

The first stage where the hemihydrate is formed takes place instantaneously in the presence of water vapor,

Fig. 1 Stepwise sorption isotherm for a hypothetical substance.

whereas the second stage requires a matter of weeks or months to reach completion, depending on the humidity at which the hemihydrate is stored (12).

Finally, the critical relative humidities are dependent on the nature of the solid. For example, the spontaneous dissolution process has been observed for many water-soluble substances at relative humidities significantly below that associated with a saturated solution of the substance in water (5). Van Campen et al. (13–15) have examined the moisture sorption kinetics of deliquescent solids at relative humidities above what they term the “critical relative humidity” (RH_o), where adsorbed water takes on the character of condensed water and serves as a solvent. It is important to recognize that a highly undesirable process such as deliquescence can occur when it may not be expected (e.g., when $RH_o < RH < RH_s$).

In all the previous examples, the process was absorption, and water ultimately had access to the entire solid; variations in particle size, and consequently, surface area, would not effect the profile. In many of the subsequent examples, not only is surface area a determinant of moisture content, but perturbation of the solid can occur during sorption to produce unexpected and dramatic effects.

Brunauer (16) organized the experimental isotherms observed for vapor sorption into the now classical five groups, Types I to V. Brunauer et al. (17) presented a unified theory of multilayer physical adsorption that was purported to describe all types of isotherms. Numerous texts present detailed discussion of the basis for this theory. In the context of this discussion, capillary condensation will not be considered and the focus will be Types I, II, and III behavior. Fig. 2 is a graphical representation of these three types, generated from Eqs. 3–5.

Type I isotherms, where sorption occurs on strong sorption sites, are characterized by a monotonic increase in the amount of vapor adsorbed, up to a maximum value assumed to represent a completed unimolecular layer. The Langmuir equation is generally a suitable functional relationship for $n = f(x)$, as given by

$$\frac{y}{1 + Bx} = y_m Bx \quad (3)$$

where y is the amount of water adsorbed at $x = P/P_o$, y_m is the monolayer capacity, and B is a constant, often referred to as the adsorption coefficient. Using the generally assumed value of 1250 nm^2 for the area occupied by a molecule of water on the adsorbent surface, the surface area can be estimated from y_m .

The characteristic inflection in Type II behavior occurs when multilayer sorption starts. The Brunauer, Emmett, Teller (BET) equation (17), shown as Eq. 4, can describe isotherms where multilayer sorption is evident:

$$\frac{y}{(1-x)(1+(C-1)x)} = y_m Cx \quad (4)$$

Based on the assumptions in the kinetic derivation of the BET equation, the constant C is related to the average heat of adsorption in the first layer. Type III isotherms occur when this value is low.

Application of the BET equation to experimental data has become the standard method for surface area determinations. The constants are determined from data

Fig. 2 Hypothetical Type I, II, and III sorption isotherms with a monolayer capacity of $y_m = 5$.

at low humidities (5–30% RH). Based on these parameters, the BET equation almost always overestimates the amount of water associated with the solid at high humidity.

As 100% RH is approached, the BET theory predicts that the amount of water adsorbed will be infinite. As the influence of the solid surface does not extend indefinitely, it should be expected that a finite number of molecular layers would be adsorbed (presuming that the solid is not soluble.) Many authors attribute the “infinity catastrophe” of the BET theory to the lack of consideration of lateral adsorbate interactions (18–20).

Ostensibly the constant C relates to the state of water associated with the solid; however, the simplistic assumptions (all molecules in the second and higher layers are assumed to have the same character as bulk water and horizontal interactions between molecules are ignored for all layers) used in the derivation preclude really useful thermodynamic information.

Equation (5), a modification of the BET equation which assumes a third thermodynamic state for the adsorbate, was developed independently by Guggenheim et al. (21).

$$\frac{y = y_m C K x}{(1 - Kx)(1 + (C - 1)Kx)} \quad (5)$$

where K is a constant that accounts for the intermediate state between tightly bound water in the first layer and bulk liquid. This model is also simplistic but it does fit data at high relative humidities better than the BET equation. Eq. 5 is termed the GAB equation (22).

All of the equations presented thus far are single-valued relationships between the amount adsorbed and the pressure of water in the atmosphere. However, hysteresis is frequently observed. When a sample that has reached a specific equilibrium moisture content is exposed to lower relative humidity, desorption occurs. In many cases, adsorption and desorption isotherms are not superimposable.

Fig. 3 is an example of a Type II sorption isotherm with hysteresis. Although the etiology of hysteresis has been the subject of many discussions (23–30), the phenomena usually can be attributed to

- Irreversible perturbation of the solid, that is, sorption can increase (swelling) or decrease (collapse of a freeze-dried cake) the surface area;
- Kinetic origin, that is, the new equilibrium position has actually not yet been reached; and
- An actual change in state of the adsorbate.

Most individuals recognize hysteresis in terms of a substance having different moisture contents at a specified

Fig. 3 Type II isotherm with hysteresis.

Fig. 4 Moisture sorption isotherm for lactose. (Adapted from Ref. 10.)

Fig. 5 Moisture sorption isotherm for compressible sugar. (Adapted from Ref. 31.)

relative humidity (CD in Fig. 3). The implications of this situation are obvious: the moisture content of a material depends on its history of exposure to different relative humidity conditions. Controlling relative humidity can only insure that the moisture content lies within the range specified by the isotherm. The other aspect of hysteresis is that substances with equal moisture contents can have adsorbed water with different chemical activity (AB in Fig. 3).

Although the sorption isotherm is fundamental to the characterization of moisture interaction with water, it is generally not possible to make any judgments about the effect of water on the substrate from the isotherm alone. For example, it is not possible to determine if an increase in moisture content is due to multilayer adsorption, swelling of the substrate, or some combination of the two.

Sorption isotherms for lactose are shown in Fig. 4, compressible sugar in Fig. 5 (31), microcrystalline cellulose in Fig. 6 (32), and aspirin in Fig. 7 (3). The isotherm for lactose has been adapted from data in the *Handbook of Pharmaceutical Excipients* (10); the step-wise isotherm expected is not evident. The dashed line in Fig. 4 is based on the statement that the monohydrate forms at 70% RH.

Fig. 6 (a) Moisture sorption isotherm for microcrystalline cellulose: adsorption and desorption. (Adapted from Ref. 22.) (b) BET and GAB equations describing the adsorption branch.

Compressible sugar NF is an example of a material that very slowly sorbs relatively small amounts of water, with a resulting isotherm that is not smooth. The adsorption isotherm was generated from a sample that had been carefully preconditioned to remove moisture. The dramatic difference between the desorption and adsorption branches of the isotherm indicates that water forms a

Fig. 7 Moisture sorption isotherm for aspirin. (Adapted from Ref. 3.)

hydrate-like phase (31). Zografi and Kontny (22) have demonstrated that almost all of the water taken up by compressible sugar is associated with the maltodextrin.

Moisture sorption of microcrystalline cellulose has been studied extensively (22, 32, 33). Fig. 6a includes the sorption and desorption studies for microcrystalline cellulose. The inserts are plots of moisture content versus time, which approximately represent the kinetics of sorption and desorption at each humidity. The equilibrium adsorption isotherm (Type II) has been fit to the BET equation ($C = 16.48$, $y_m = 0.033$ g/g solid) and this curve is presented in Fig. 6b along with a curve described by the GAB equation by using the same monolayer capacity.

The isotherm for aspirin would be classified as Type III, indicating a low affinity for water followed by multilayer sorption. These four isotherms cover a broad range of moisture interaction with solids of pharmaceutical interest.

ANALYTICAL METHODS

There is no single analytical method that suffices in the characterization of moisture associated with solids. The best approach is a judicious combination of the following techniques.

In this era of automatic titrators, microprocessor-controlled thermal analysis, and definitive spectral techniques, one of the most powerful techniques, that is, optical microscopy, is frequently overlooked. The value of direct sample observation, preferably while it is exposed to different relative humidities, cannot be overstated. In the author's laboratory, a plexiglass chamber was constructed that can be placed on the stage of the microscope, through

which air of known humidity can be circulated. This simple technique has been very useful in examining the swelling (or lack) of disintegrants (34) and the influence of very hydrophilic excipients in combination with a moisture sensitive drug (3).

In a moisture determination by the physical separation of water from the solid, it is important to recognize that free and bound moisture must be dissociated from the solid by an applied stress, using

where x is the moles of water initially associated with the solid, y the moles of water still associated with the solid, and $(x - y)$ the amount of water released as a consequence of the stress. The stresses used differ according to the conditions (e.g., high temperature, low vapor pressure, anhydrous solvent systems). Hence, the moisture contents determined by different methods may very well be different. There is no guarantee that $y = 0$, and no reason to expect that y has the same value for different methods.

An equally important consideration is the fact that these stresses are different than those that may be responsible for moisture release during manufacturing or within the product after manufacture. One should approach the determination of moisture content with the disconcerting realization that different methods can produce different results and that none of these results may be relevant.

Thermal Methods

Thermal gravimetric analysis (TGA) is undoubtedly the most widely used method of moisture content determination. The sensitivity and sophistication of TGA instruments ranges from the classical moisture balance (LOD) to specially designed microbalances enclosed in chambers that may be evacuated. Microprocessor control of the temperature increase has led to more reproducible and discriminating information.

The result of a TGA of dicalcium phosphate dihydrate is shown in Fig. 8. The profile represents the weight loss with increasing temperature ($1.5^\circ\text{C}/\text{min}$) in an environment containing a desiccant. The total weight loss is the difference between the initial weight and the final constant weight of the dry solid. There are two regions in the profile, the first beginning at about 90°C and the second at about 170°C . Assuming that the only volatile component is water, calculations indicate $W_D = 0.228$ (22.8% MC), with W_D values of about 0.042 and 0.186 associated with Regions I and II, respectively.

Fig. 8 Thermal gravimetric analysis of dicalcium phosphate dihydrate.

The profile in Fig. 8 is characteristic of a crystal hydrate, showing discrete regions of moisture loss occurring at relatively high temperature. This particular profile is consistent with the dehydration scheme shown in Eq. 7.

Differential scanning calorimetry (DSC) is a thermal method that measures the energy change accompanying a nonadiabatic process. A small sample of the moist solid contained in a metal sample container is exposed to a controlled increase in temperature. Water dissociated from the sample is swept out of the heating chamber by a nitrogen stream and the dynamic energy consumption (mcal/sec) required to keep the sample at the same temperature as an empty sample container is recorded. When the temperature is increased at a constant rate, the

area under the DSC curve reflects the energy, in the form of heat, associated with the phase change.

The DSC profile for dicalcium phosphate dihydrate (Fig. 9 curve A) includes two endotherms consistent with the dehydration scheme shown in Eq. 7. (In all DSC plots reported here, endotherms are positive deflections from the base line.) It should also be noted that the energy change measured is not specific for water; it includes, for example, energy consumed or released because of changes in crystal structure. Thus, it is generally not appropriate to estimate moisture content from the enthalpy change for dehydration and the specific heat of vaporization of water.

A common error is to look at temperature profiles (TGA or DSC) and conclude, for example, that no water is released from dicalcium phosphate dihydrate at 50°C. It is important to recognize that this is a dynamic test with a large temperature increase examined over a relatively short time periods. Exposure of dicalcium phosphate dihydrate at 50°C may indeed drive off water of hydration; the system is not held at any particular temperature and the relative rate of moisture loss is slow.

Curve B in Fig. 9 is the result of an interesting test on a sample of anhydrous dicalcium phosphate that had been exposed to 100% RH for three months. Clearly, some of the moisture acquired by the solid was converted into water of hydration. However, the broad endotherm from about 50 to 130°C represents the energy consumed in the dissociation of water that is not part of the crystal structure. The existence of two states of water in the same solid raises a number of questions pertaining to the wisdom of using anhydrous dicalcium phosphate as an excipient for moisture-sensitive drugs.

The TGA profile for lactose is shown in Fig. 10. This profile is consistent with a monohydrate that loses its water of hydration in one step. DSC data for lactose are shown in

Fig. 9 Differential scanning calorimetry of dicalcium phosphate samples. (A) dicalcium phosphate dihydrate; (B) anhydrous dicalcium phosphate with adsorbed moisture.

Fig. 10 Thermal gravimetric analysis of lactose monohydrate.

Fig. 11 Differential scanning calorimetry of lactose samples. (A) anhydrous lactose; (B) lactose monohydrate; (C) anhydrous lactose with adsorbed moisture.

Fig. 11. Scan A for anhydrous lactose is rather uneventful, although comparison with the other scans seems to indicate the presence of a small quantity of water. Scan B is for lactose monohydrate; the single water of hydration is lost at approximately 135°C, with decomposition occurring at about 200°C. Scan C is for an anhydrous lactose sample that had been exposed to 100% RH for three days. Clearly, the water sorbed by anhydrous lactose was quickly and completely converted to water of hydration.

Thermal analyses of microcrystalline cellulose reveal distinctly different results. The TGA (Fig. 12) shows a loss of moisture at low temperature and a reasonably monotonic decrease that does not indicate discrete stages of hydration. The DSC (Fig. 13) shows a broad region of moisture loss at temperatures well below the boiling point of water.

Fig. 12 Thermal gravimetric analysis of microcrystalline cellulose.

Fig. 13 Differential scanning calorimetry of microcrystalline cellulose.

The principal advantage of the thermal methods is convenience; however, these analyses are not specific for water, and exposure to high temperature may be an unrealistic stress or alter the sample. An acceptable determination of moisture content using a thermal method provides a result with minimal residual moisture and only minor alteration of the solid. Thermal methods can be combined with a specific titration of water by bubbling the evolved gas from TGA or DSC through the titration medium.

Karl Fisher Titration

For over 60 years, the specific titration of water has used a reagent developed by Karl Fisher, which consists of iodine, sulfur dioxide, and pyridine in methanol. The Karl Fisher titration of water is addressed in most analytical chemistry texts and is not presented here. A brief review with a pharmaceutical perspective has recently been published (35). However, the advantages and disadvantages of this method for the characterization of water associated with solids are discussed later.

In its simplest form, the Karl Fisher titration is a one-point determination of moisture content. The principal advantage is specificity for water. It is also a non-thermal method, which is very sensitive and can be easily automated. The main disadvantage is that the solid must dissolve in the titration medium to be sure that the total amount of moisture is released. If the analysis is carefully designed in such a way that moisture is "extracted" from the solid to the same degree each time, accurate and reproducible results can be obtained for solids that do not dissolve.

With automation, the Karl Fisher titration provides a titration kinetics profile (e.g., milliliters of titrant vs. time).

Fig. 14 Normalized Karl Fisher titrations of dicalcium phosphate dihydrate; (A) unmilled form; (B) milled form.

If the rate of water release from the solid is the rate-limiting step, the kinetics of the Karl Fisher titration profile can provide indirect information about the state of water associated with the solid. Fig. 14 shows the titrations of two different samples of dicalcium phosphate dihydrate. Here, and in the titration profiles in Fig. 15, the data have been normalized in such a way that each titration ultimately consumes 25 mL of reagent. This normalization is analogous to increasing the sample size in such a way that it contains an amount of available water which would require 25 mL of reagent to neutralize. Also, the direct titration of water can be finished in less than 90 s.

The titration profiles for dicalcium phosphate are not monotonic, but exhibit stages of dehydration consistent with the scheme shown in Eq. (7). It is also evident that the release of moisture is faster from the milled form (Fig. 14,

Fig. 15 Normalized Karl Fisher titration for dicalcium phosphate; (A) milled sample; (B) anhydrous sample with adsorbed moisture.

curve B) of the excipient. This is consistent with the increased total surface area and shorter diffusional path expected with smaller particle size.

In Fig. 15, Karl Fisher titration of anhydrous dicalcium phosphate, which had been exposed to 100% RH for 3 months (curve B), is compared to with that of milled dicalcium phosphate dihydrate (curve A). The adsorbed water, which was not incorporated into the crystal lattice, was released from the solid very rapidly.

Results of normalized Karl Fisher titrations for lactose monohydrate and microcrystalline cellulose both present profiles not significantly different from water, indicating a very rapid release of moisture.

Spectroscopic Methods

The most useful spectral methods for the characterization of water in solids are Fourier transform infrared spectroscopy (FTIR), nuclear magnetic resonance (NMR), and powder X-ray diffraction (XRD). A thorough treatment of these methods is not given here; instead the example of ampicillin presented by Brittan, et al. (36) is summarized.

Hydrates normally form crystal structures (pseudo-polymorphs) that differ from the anhydrous form. Different powder XRD patterns of ampicillin in the anhydrous and trihydrate forms are shown in Fig. 16.

Fig. 16 Partial X-ray diffraction patterns of ampicillin samples. (Adapted from Ref. 36.)

Although moisture contents often present values that are close to being stoichiometric, X-ray confirmation of the differing crystal structure should be a requisite for designation as a hydrate.

The X-ray method is not just useful from the qualitative perspective. In samples that contain both anhydrous and hydrate forms, diagnostic regions of the pattern can be identified, and the relative areas of peaks in these regions may be used to establish the relative amounts of each phase (36).

Infrared analysis of water associated with a solid centers on an assessment of the degree to which the environment influences the stretching frequency associated with the —OH group. The —OH stretching mode for free water in the gaseous state has a characteristic energy of 3655 cm^{-1} . The frequency of this stretching is lowered when water is condensed and/or bound. Ice has a characteristic —OH stretching frequency of 3400 cm^{-1} . By comparison of the FTIR spectra for the anhydrous form with those of the sample with water, the —OH bands for water can be identified. The distinctive, sharp peak for crystalline water is shown in Fig. 17; when water is present in several states, multiple bands may be seen in the spectrum.

Fig. 17 Partial FTIR spectra of ampicillin. (Adapted from Ref. 36.)

Fig. 18 Solid-state ^{13}C NMR spectra of ampicillin samples. (Adapted from Ref. 36.)

Solid-state NMR is a method that promises to increase the understanding of the state of water in solids and its specific influence on the chemicals of interest. In Fig. 18, for example, it is clear that the solid-state ^{13}C NMR spectra of ampicillin trihydrate is a very different form than that for the anhydrous form. Although three carbonyl resonances present in the anhydrous form (169.7, 172.7, and 174.6 ppm), it is interesting that only two (170.4 and 172.6 ppm) are fully resolved in the hydrate form (33). Thus, in the latter, two of the three carbonyls are equivalent. Evidence also exists for differences in carbons in the aromatic ring based on the presence of water of hydration.

INFLUENCE OF MOISTURE ON PRODUCT AND/OR PROCESS ATTRIBUTES

No attempt will be made to provide a comprehensive summary of the numerous studies that have been conducted and which show how water influences the processing and stability of pharmaceutical solids and dosage forms. For more information, the reader is referred

to some classical texts (10, 27, 37, 40, 41), recent general articles on the subject (5, 11, 42, 43), and those with specific emphasis on the role of water on stability (44–47) or compaction properties (48–52).

In an earlier section, the potential for a water-soluble substance to deliquesce was discussed. The emphasis here is on less obvious effects of moisture on solid dosage forms, and three associated areas that link to information presented earlier in this article are discussed: 1) moisture-induced changes in the state of the solid, 2) the effect of moisture on the performance of excipients in the manufacture of compressed tablets, and 3) the chemical stability of bioactive agents alone and in combination with excipients.

Moisture-Induced Changes

That moisture can have a dramatic effect on the physical character of a substance has been demonstrated recently by Carstensen and Van Scoik (51). Amorphous sucrose spheres were prepared by lyophilization and placed in an environment at 33% RH. Lyophilization characteristically produces a highly porous, amorphous solid cake. As shown in Fig. 19, its moisture content increases considerably in the first few days of the study. However, the moisture absorbed by the porous amorphous sucrose phase eventually caused a collapse of the structure and a commensurate reduction in moisture content because of the dramatic decrease in available “surface.” Not only did the physical structure change from a loose to a more dense

Fig. 19 Moisture uptake by amorphous sucrose at 23°C at 33%RH. (Adapted from Ref. 51.)

amorphous structure, but also the amorphous sucrose was shown to convert to the crystalline form at a rate that was dependent on relative humidity. This example is consistent with the increased emphasis being placed on changes in state of the solid as a result of sorption. One of the difficulties associated with a thermodynamic treatment of solids is the problem of dealing with changes in surface area as a continuous variable. An early thermodynamic treatment to address this problem was presented by Copeland and Young in 1961 (53). These authors considered a change in the number of moles of adsorbent as an addition or removal of particles with the same specific surface area, and, therefore, presented a basis for treating thermodynamic properties of powder systems as continuous functions. Wu and Copeland (54) used this approach in the characterization of barium sulfate. They found clear evidence to discount the “inert” adsorbent theory and stressed that even though thermodynamic variables of adsorbents are generally smaller than these for adsorbates, this can be misleading. Adsorbent properties are average properties of the respective component. When the adsorbed moisture is homogeneously distributed within the solid, this estimate is reasonable. However, if the process is adsorption and only the first few layers of the adsorbent are affected, the thermodynamic changes would be dramatically increased. Very few pharmaceutical studies involve the determination of thermodynamic properties of the adsorbent which is a promising area for further research.

The need to address changes in adsorbent is discussed by Zografi (5). He observes that water absorbed into the bulk structure of a solid can act as a plasticizer and depress the glass transition temperature. At temperatures above the glass transition point, the mobility of molecules or segments of molecules in the system increases (5). The change from the “glassy state” to the “rubbery state” can account for a number of physical chemical processes of pharmaceutical interest, including the collapse and subsequent crystallization of lyophilized cakes (see example previously), direct compaction properties, powder caking, permeability of coatings and packaging materials, and solid-state chemical stability (5). Recognition of this fact has been the single greatest recent advance in establishing a framework for understanding and predicting the impact of moisture.

Zografi and Kontny (22) corrected the experimentally determined monolayer capacities of microcrystalline cellulose for degree of crystallinity and found reasonably consistent values. This result supported the conclusion that water in microcrystalline cellulose is confined to the noncrystalline regions (22, 56).

Fig. 20 Compression force vs. hardness plots for microcrystalline cellulose tablets with 0.07 and 5.1% MC. (The points represent individual tablets collected during manufacture.)

Effect of Moisture on Excipients and Tablet Manufacture

The bulk properties of celluloses are generally influenced by adsorbed moisture (58, 59). The effect of the change in bulk solid properties for microcrystalline cellulose has been demonstrated by a tableting operation in a very simplistic manner. Dry microcrystalline cellulose (%MC = 0.07) was compared with material with a moisture content above that associated with completion of the monolayer (%MC = 5.1). A thermodynamic picture of the character of water in these samples can be based on the adsorbate thermodynamic properties: $\Delta H > 3.5$ kcal/mole (14.65 kJ/mole), $\Delta G > 2.3$ kcal/mole (9.6 kJ/mole), $\Delta S < 4.12$ entropy units (e.u.) per mole with the dry solid, and

Fig. 21 Hardness vs. compression pressure for compressible sugar with different moisture contents. (Adapted from Ref. 31.)

$\Delta H = 1.5$ kcal/mole (6.27 kJ/mole, $\Delta G = 0.53$ kcal/mole (2.21 kJ/mole), $\Delta S = 3.35$ e.u./mole for moisture at the 5.1% level, or 1.5 times monolayer capacity. (The differential entropy goes through a maximum near the level where a monolayer is completed, and the large difference in free energy between the two states can be accounted for primarily in terms of the bonding of the water to the solid.)

In each case, preconditioned material was placed in the hopper of an instrumented tablet machine and the performance of these two materials was compared at constant machine settings. The sample with 5.1% MC produced tablets that weighed slightly less (an effect on flow and bulk density), and as a result were exposed to lower compression force. However, the moist microcrystalline cellulose resulted in harder tablets, even though it had been exposed to lower compression force. The loci of points on the compression force versus hardness profile (Fig. 20) for the tablets indicate a different fundamental behavior for the two materials.

In a similar, yet more extensive study, the compaction of compressible sugar was examined for materials preconditioned at different relative humidities. The hardness versus compression profiles (Fig. 21) for these samples show a group of lines whose slope appears to be a function of moisture content. This relationship is also demonstrated in Fig. 22, where the slope is used as a compressibility index. This index is a linear function of moisture content; samples with “desorbed” moisture did not differ from those with adsorbed moisture.

Fig. 22 Compressibility of compressible sugar as a function of moisture content. (Adapted from Ref. 31.)

Chemical Stability of Bioactive Agents

Despite recent advances in understanding the influence of moisture on the physical state of the solid, it is perhaps the effect of sorbed moisture on the chemical stability of moisture-sensitive drugs that is most important, particularly because many new bioactive agents are expensive moisture-sensitive proteins.

The literature related to the study of the influence of moisture on the properties and stability of proteins is extensive and growing rapidly. The examination of water associated with proteins and polymers is relevant to the pharmaceutical scientist dealing with the formulation and processing of small drug molecules as well because many excipients used belong in this large-molecule category. A review of protein stability from the pharmaceutical perspective has been presented by Hageman (44). He ascribes the effect of water content and activity on the solid-state stability of proteins to

- Changes in dynamic activity.
- Changes in conformational stability.
- Participation of water as a reactant or inhibitor, and
- Participation of water as a medium for mobilization of reactants.

Using an analysis of the hydration data of lysozyme and other proteins, Hageman (44) describes critical ranges of hydration based on certain properties of bound water (carboxylate absorbance at 1580 cm^{-1} , amide-I shift at 1660 cm^{-1} , OD stretching frequency at 2570 cm^{-1} , specific heat capacity, diamagnetic susceptibility). Below monolayer capacity, these physical properties of water do not change significantly, and this water has very little

Fig. 23 Effect of sorbed water on the reaction rates of bimolecular reactions in the solid state. (Adapted from Ref. 43.)

mobility. Between 6% and 25% water, the properties of bound water change dramatically, above 25% water, the properties of bound water are similar to bulk water.

In Fig. 23, the role of moisture in bimolecular reactions is classified by Hageman into three cases. The increases in reaction rate are attributed to a change in state of the water associated with the solid as reflected by a lower effective viscosity. In Case I, there is a continual increase in reaction rate with increasing water content above the monolayer. When all the reactant has been solubilized and further water dilutes the medium, Case II results. If the dilution is extensive, or if water is a product inhibitor of decomposition, a rate reduction can be observed (Case III). Case III behavior is an example of the effect of moisture on the progress of the Malliard reaction for the glucose-containing formulations of α -N-acetyl-L-lysine, poly-L-lysine, insulin, casein, and plasma proteins (43). The fact that there can be a maximum degradation rate at a humidity other than 100% RH is observed in other situations as well.

The presence of excipients in a formulation can influence product stability. The conceptually appealing strategy of including a “moisture scavenger” in a formulation is based on this. In glucose-containing systems, it was demonstrated that liquid and solid humectants can influence the mobility of water in the system. The location of the maximum rate of reaction was found to vary from 40% to 80% RH, depending on the additives (43). The addition of liquids such as glycerol or propylene glycol lowered the mobilization point and facilitated the reaction at lower humidities. The addition of the solid humectant sorbitol reduced the reaction rate dramatically by decreasing free water for mobilization of reactants.

Carstensen (11) has presented a summary of the effects of moisture on the stability of smaller molecules by addressing three cases: decomposition with nondepleting moisture, simultaneous decomposition in the solid and dissolved states, and decomposition with limited amounts of water. In the context of this discussion, emphasis here is placed on hydrolytic degradation processes.

The first case with abundant moisture was initially modeled by Leeson and Mattocks (55) by assuming that the solid particle was surrounded by a layer of moisture sufficiently mobile to permit dissolution of the drug substance. If the layer remains saturated with drug, this approach yields an apparent zero-order degradation process given

$$-\frac{dM}{dt} = kS[\text{H}_2\text{O}] \quad (8)$$

where $-dM/dt$ is the rate of drug loss, k is a rate constant appropriate for the order of the reaction, S is the saturation

concentration of the drug in the layer, and $[H_2O]$ is the concentration of water. Although this simple approach often suffices in form to describe data observed in a stability study, it should not be expected to account for the effects of moisture present in the different states described previously.

The degradation of aspirin powder after 120 days at 100% RH and 25°C, for example, was found to be more than ten times greater than what would be expected based on suspension data (48). In addition, the actual rate of aspirin degradation has been found to increase with time (60,61). Carstensen presented a theory to describe this nonlinear behavior based on the fact that the formation of salicylic acid actually exposes moisture adsorption sites of higher energy on aspirin (61), thereby leading to the acquisition of more water. This explanation accounts for an increase in rate with time, but does not explain why the rate is higher for the powder than a suspension where the supply of water is in huge excess. This increased rate could be due to specific acid catalysis in a film of relatively small volume where the pH is dramatically affected by the hydrolysis itself (61).

Finally, the complicated situation faced when a moisture sensitive drug is combined with an hydrophilic excipient is shown in Fig. 24. In this study, aspirin was combined with 4% of the disintegrant and stored for 120 days at 25°C at the respective humidity. The moisture

contents stabilized within the first few days, and the degradation results are presented as moles of the degradation product salicylic acid per mole of water. Point A is the result for aspirin powder alone at 100% RH.

These results demonstrate many of the points presented here. At 100% RH, the reaction rate is lower than that expected for croscarmellose and sodium starch glycolate, because the disintegrants swelled and in doing so diminished the available moisture (crospovidone does not swell). Normalizing based on the total moisture present overstates the amount of water available to react and underestimates the actual reaction rate. At the other extreme (20% RH), the analysis is also biased by overstating the amount of water available, but for a different reason. The water associated with the system here is tightly bound to the disintegrant and not available. At intermediate humidities, depending on the excipient, the observed rate for degradation of the solid is higher than expected. This behavior may be a consequence of the activated sorption process and a specific acid catalysis described by Carstensen (61). Nevertheless, results of this sort are disconcerting for the product development pharmacist interested in making a stable tablet that disintegrates quickly.

SUMMARY

Real progress has been made in the last 10 years, providing pharmaceutical scientists with a solid basis for understanding the interaction of water with solids of pharmaceutical interest. Much of this progress has been the consequence of a paradigm shift: the model of the solid as an inert substrate is almost never valid. Further characterization of the state of water in solid-water systems may ultimately provide a basis for the design of stable formulations and permit the establishment of performance-based specifications for pharmaceutical excipients.

MIXING AND SEGREGATION IN TUMBLING BLENDERS

Troy Shinbrot

Fernando J. Muzzio

Rutgers University, Piscataway, New Jersey, U.S.A.

MOTIVATION

Mixing of solids is essential to many industries, including pharmaceuticals, ceramics, metallurgy, chemicals, food, cosmetics, coal, and plastics. To give an idea of the magnitude of applications involving granular processes, U.S. worldwide production alone accounts for over a trillion kilograms of granular and powdered products annually, most of which must be uniformly blended to meet quality and performance goals. In this article, we present an example-oriented overview of current understanding of mixing and segregation mechanisms that are of importance to powder blending operations. We focus on industrial tumbler designs, which simultaneously comprise the bulk of solids blending operations and represent the systems for which predictive modeling appears to have the greatest potential. We direct the reader to existing literature sources (e.g., Harnby, 1997) for information on more specialized blending equipment. Numerous distinct mechanisms for both mixing and demixing of granular materials have been catalogued including convection, diffusion, shear, percolation, etc., and in most applications, several mechanisms act concurrently and interact in complex, and currently poorly understood, ways. Thus the mode by which powders are loaded into blenders of common design can alter the time needed to homogenize them by two orders of magnitude. Given that a certain blender can be designed to deliver acceptable performance in the laboratory, we have no consistent a priori mechanism to scale up the process and achieve the same performance in blenders of industrial size. Although comprehensive and predictive understanding of practical blending problems still remains a long-term goal, it has recently become possible to define models that generate respectable agreement with observations in practical granular devices (e.g., 3D tumblers), and methods have become sufficiently refined that systematic techniques to analyze new products and equipment are available, either off the shelf or as research-ready hardware.

FUNDAMENTALS

Research on granular flow and blending roughly can be divided chronologically: prior to about 1990, industrially usable results were mostly empirical (e.g., in experiments using a particular blend in a specific device), and fundamental research was largely analytic (e.g., using continuum approximations to the granular state applicable only to one phase of granular behavior). Although important progress was made into developing specialized engineering solutions and fundamental physical properties of granular systems, little generally applicable knowledge was attainable using either approach. Since that time, computational and methodological advances have permitted quantitative evaluations of granular flow, transport, and mixing at an unparalleled level of detail and accuracy. In this Section we have reviewed progress on tumbling flow and blending phenomenology that has led to the development of the best predictive models existing.

Definition of the “Granular State”

A chief limitation, and the principal area of opportunity for the future, in developing predictive understanding of granular flows is the coexistence of multiple, history-dependent, granular states. Within a device—be it a tumbler, a high shear intensifier, a mill, a fluidized bed, etc.—granular material can, and typically will, exhibit multiple rheologically different phases that vary nontrivially and often with profound consequences as a function of minor changes in material or environmental variables. This is a particular problem in the pharmaceutical industry, where products may be developed in dry, northern, latitudes and produced in wet, equatorial climates. Both hygroscopic excipients and actives behave very differently in these two environments, and blending regimens that work in one may fail in the other. Moreover, even within a single well-controlled bench-scale device, multiple phases are typically present. The tumbling blender is a case in point.

In Fig. 1, a deceptively common outcome of an attempt to blend dissimilar materials is shown, here of grains

Fig. 1 “Left-right” segregated state, here in a transparent V-blender, between larger (dark) and smaller (light) grains. This state occurs spontaneously at high fill levels and fast tumbling speeds in many tumbler designs.

differing only in size and color. In this transparent 4-L capacity^a V-blender, we have tumbled equal volumes of small light-gray and larger black grains at 6 rpm for 200 revolutions. The visibly segregated state is only one of several distinct segregated configurations that form spontaneously and reproducibly in all common blender geometries and scales, and persist despite the practitioner’s best efforts at modification of process parameters. Developing cures for this type of problem demands a systematic understanding of why segregated states occur in the first place, so that the cause of segregation can be addressed directly. This understanding in turn requires an analysis of the different granular behaviors seen during the tumbling operation.

A first step in the analysis of granular behaviors is the characterization of the different granular phases that are inevitably present during flow. Grains, unlike common fluids, must “dilate” in order to flow, that is, grains in the static state are interlocked, and cannot move without separating. The locations and timing of dilation can be quite complex, but once dilation occurs, the overt granular behavior seen remains static and solid-like far from the regions of dilation, and becomes respectively glassy (disordered), fluid-like, or gas-like near the shear interface as the shear rate increases. The modifier, “like,” is important to include, because a solid-like region is not truly elastic as it transmits stress along irregular compressive chains, undergoes slow creep and settling on time scales ranging from seconds to hours, and can solidify into a rigid “cake” over time scales of days to months. Likewise the fluid-like phase transmits shear discontinuously both in

space and time, and does not obey Navier–Stokes equations, and the gas-like phase is far from equilibrium and is not characterized by Maxwell–Boltzmann statistics. It is the differences between qualitative behaviors of different regions of a granular bed at different times and between any one of the behaviors and accepted models for flow and dispersion that make predictive understanding of even the simplest granular systems challenging.

Despite the intrinsic difficulties in developing an all-encompassing model for granular flow, important blending problems of practical interest have been effectively analyzed using model-based, computational, and semiempirical means. The current understanding of granular blending and demixing is summarized in subsequent sections.

Elementary Two-Dimensional Mixing Mechanisms

In tumbling applications, dilation and flow principally play out near the unconstrained upper surface of a granular bed, and the bulk of grains beneath are thought to remain nearly motionless during rotation of the blender. This simplified picture changes for some blender varieties (e.g., Fig. 2b), but predictive models for blending in most common blending geometries can be derived by disregarding all transport beneath the free surface. In the following sections, the best existing models and methods are summarized and their application to common tumbler designs is described.

Although it differs significantly from more complex practical blender geometries (see sections on Competitive Patterned Demixing and Examples), the horizontal drum tumbler has a simple geometry and therefore provides a useful environment for a first analysis of granular mixing and demixing. A horizontal drum mixer is the simplest form of a tumbling blender and it is used in many pharmaceutical, chemical, and metallurgical industries in the form of ball mills, dryers, rotary kilns, coating pans, and mixers.

Flow regimes

Flow in rotating drums has been described qualitatively in terms of regimes such as slipping, avalanching, rolling, cascading, cataracting, and centrifuging.

Slipping: The slipping regime occurs when the granular bed undergoes solid body rotation and then slides, usually intermittently, against the rotating tumbler walls. This most frequently occurs in simple drums that are only partially filled, and is often counteracted by including baffles of various designs along the inner walls of the tumbler. Although the slipping regime is not important for blending purposes per se, it is encountered even in effective blending systems, and an evaluation of the

^aThe reader should note that “capacity” customarily refers to a fraction (generally 60%) of the total interior volume of a blender.

Fig. 2 Schematic of dilation mechanism that is a prerequisite for the flow of solids. (a) In undisturbed state, grains are interlocked and behave much like an ordinary solid. (b) A granular bed dilates in response to applied shear, and can then flow. (c) In the flowing state, the bed can form distinct crystalline, glassy, fluid-like and gas-like phases. The crystalline phase is regular and ordered, the glassy phase is disordered but static, the fluid-like state flows but exhibits enduring contacts, and the gas-like state is characterized by rapid and brief interparticle contacts.

number of times a bed is turned over per tumbler revolution will often reveal the presence of some slipping.

Avalanching: A second regime seen at slow tumbling speeds is the “avalanching” flow regime, also referred to as “slumping.” In this regime, flow consists of discrete avalanches that occur as a grouping of grains travels down the free surface and comes to rest before a new grouping is released from above. The avalanching regime is not seen in large tumblers (larger than a few tens of centimeters in diameter), but is an instructive case because flow and mixing can be solved in closed form for simplified drum geometries, and lessons from this regime can, with due caution, be carried over to more realistic systems.

To analyze this problem, one only need observe that if the angle of repose at the free surface immediately before an avalanche is ϑ_i , and after an avalanche is ϑ_f , then the effect of an avalanche is to carry a wedge of material in the angle $\vartheta_f - \vartheta_i$, downhill, as sketched in Fig. 3a for an idealized 2D disk blender. The same caricature applies at

Fig. 3 (a) Avalanching flow in an idealized disk tumbler transports grains from an uphill wedge to a downhill wedge as the free surface relaxes from an initial angle ϑ_i to a final angle ϑ_f . This implies that global mixing occurs in quadrilateral regions where grains within one wedge intersect with a second wedge. (b) Consequently, tumblers mix more efficiently at low fill levels than at high, and global mixing nearly stops at 50% fill. (c) At fill levels above 50%, a core develops that does not visit the avalanching surface and, therefore, does not experience transport or mixing.

all fill levels, and one can readily use this model to make several concrete predictions. First, mixing occurs during avalanches through two distinct mechanisms: one, particles within a wedge rearrange during a single avalanche, and two, particles rearrange globally between wedges during successive avalanches. Second, at 50% fill (Fig. 3b) no two avalanching wedges intersect, so no global mixing between separated regions can exist, and mixing must be slow. Third, since flow occurs only near the avalanching surface, at high fill levels a nonmixing core necessarily develops (Fig. 3c). Although this model is oversimplified and neglects material variations, boundary effects, and other important physics, these conclusions carry over to more realistic tumbling systems.

Rolling: At higher tumbling speeds, discrete avalanches give way to continuous flow at the surface of the blend. Grains beneath the cascading layer rotate nearly as a solid body with the blender until they reach the surface. One can solve for flow and transport subject to certain simplifying assumptions in this regime as well. For this solution, one assumes that the grains are so small as to be regarded as a continuum and one takes the free surface to be nearly flat, as sketched in Fig. 4a. The interface between the flowing layer and the supporting bed beneath has been determined experimentally and through detailed computations to be roughly parabolic in shape (1) and by demanding mass conservation at this interface one can construct continuum flow equations for this system (2). If one simulates the mixing in an idealized disk blender of mechanically identical grains initially separated by color to left and right of a vertical central plane, one obtains the results (for a particular fill level and flowing layer depth) as shown in Fig. 4b. Corresponding experimental results are shown in Fig. 4c.

Cascading, cataracting, and centrifuging: For larger tumblers, or for tumblers rotated at higher speeds, the surface is manifestly not flat, as shown in Fig. 5 in a 1 meter diameter disk tumbler (3). This flow, termed cascading, differs qualitatively from the rolling flow solution: here the flowing layer is thin and is nearly

Fig. 4 (a) In the rolling regime, the blend separates into a flowing layer near the surface and a solid-like supporting bed. (b) By establishing simple conditions such as mass conservation, one can generate an analytic model for the flow, producing mixing patterns between initially separated and colored, but otherwise identical, grains. (c) Comparison with experimental mixing patterns using freely flowing grains in a small drum tumbler reveals substantial agreement. The snapshot in (c) is obtained from the interior of the blend using the solidification technique described in the section on Solidification in this article.

uniform in speed and thickness, and has been modeled as depth averaged, plug-like flow. As the rotation speed of the tumbler is increased, the surface becomes increasingly sigmoidal until grains become airborne, and at higher speeds yet, the grains centrifuge against the tumbler wall. These regimes are termed cataracting and centrifuging, respectively, and have not been well analyzed.

MIXING MECHANISMS IN THREE-DIMENSIONAL TUMBLERS

Although drum blenders represent a convenient paradigm for the purpose of categorizing granular behaviors, most

Fig. 5 Cascading flow occurs in large tumblers or during tumbling of fine, but freely flowing, grains. This snapshot shows a 1 m diameter transparent disk tumbler partially filled with colored $\sim 500\ \mu\text{m}$ irregular grains. The free surface is manifestly not flat, and the cascading layer is thin and nearly uniform with distance along the flowing surface.

Fig. 6 Three common tumbler designs: (a) double-cone, (b) V-blender, and (c) tote, or bin blender.

blending operations occur in more complex tumbler geometries. Three of the most common geometries used in pharmaceutical operations are the double-cone, the V-blender, and the tote blender, sketched in Fig. 6. Each of these geometries have many variants, for example symmetry can be broken to introduce cross-flow by slanting the double-cone, by elongating one of the arms of the V-blender, or by inserting baffles in a tote.

To model flow and blending in complicated geometries, particle-dynamic simulations have been implemented. In these simulations, particles are treated as individual entities with physical properties (e.g., size, static and dynamic friction coefficients, coefficient of restitution, etc.) appropriate to the problem of interest, and Newton's laws of motion are integrated for each particle. Particle-dynamic simulations are similar in concept to molecular-dynamic simulations, but include features of importance to the flow of macroscopic particles (e.g., static and dynamic friction models) in place of microscopic properties (e.g., bond strengths and chemical potentials). Particle-dynamic simulations come in many different types depending on how they treat physical parameters such as rolling friction and particle shape or numerical issues such as search algorithms and routines to maintain computational stability. Results of distinct computational simulations can differ, sometimes significantly, and the importance of experimental validation of numerical results cannot be overemphasized.

Two of the most common classes of particle-dynamic simulations are termed "hard-particle" and "soft-particle" methods. Hard-particle methods calculate particle trajectories in response to instantaneous, binary collisions between particles and allow particles to travel ballistically between collisions. This class of simulation permits only instantaneous contacts, and is consequently often used in rapid flow situations as are found in chutes, fluidized beds, and energetically agitated systems. Soft-particle methods, on the other hand, allow each particle to deform elastically and compute responses using standard models from elasticity and tribology theory. This approach permits enduring particle contacts and is therefore the method of choice for tumbler applications. The simulations described in this article use soft-particle methods

that have been validated and found to agree in detail with comparison experiments (4, 5).

Convection

Mixing in all tumbling blenders consists of a fast convective stage, driven by the mean velocity of many particles, followed by a much slower dispersive stage, caused by velocity fluctuations leading to rearrangements of individual particles. Convection in grains (as in fluids) is by far the fastest and most efficient mixing mechanism, yet at the same time it suffers from the same mixing limitations known for fluids: convective flows can, and very often do, possess barriers to mixing (e.g., islands) that do not interact with surrounding material. Two pathologies are readily observed: overfilled mixers develop elliptic, nonchaotic, islands that rotate as a unit in the center of the granular bed (discussed earlier in Section on Flow Regimes), and symmetric blenders (seen in most standard designs) exhibit separatrices that divide the flow into noninteracting sectors. Beyond this, little is known currently of details of particle flow patterns and mixing barriers in practical, three-dimensional blender geometries. There is strong evidence, though, indicating that flow bifurcations analogous to those seen in fluids may be present in granular tumblers.

Convection in the context of granular blenders refers to transport associated with flow driven by gravity (in tumbling blenders) or impellers (in intensified, ribbon, or other blenders). Convection is observed in all functioning blender geometries, and can be visualized using particle-dynamic simulations. In Fig. 7 are shown successive front and side views taken a quarter revolution apart of 20,000

Fig. 7 Rapid, convective flow seen in particle-dynamic simulation of identical but colored spheres in V-blender. Top: view from front reveals that unlike in some designs, convection in this blender drives grains axially, alternately outward toward the tumbler arms and inward toward its center. This axial flow strongly influences mixing, as described in the section on Mixing Rates in this article. Bottom: view from side indicates that transport is dominated by a spiraling flow, seen also in drums and other blenders (cf. Fig. 4).

identical but colored spheres tumbled in a V-blender in the cascading regime. These snapshots illustrate the qualitative motion produced in this blender, which causes the bed to overturn from top to bottom. Mixing due to convective flow grows linearly with time insofar as the area of an interface between differently colored layers in these snapshots or in Fig. 4b and c, grows characteristically linearly with time. Although similar qualitative behaviors are seen in all tumbler geometries, the quantitative mixing seen can differ considerably between geometries (cf. Section. Mixing rates).

Dispersion

Dispersion, also referred to as diffusion, is contrasted with convection, which can effectively intersperse grains in a tumbler within tens to hundreds of revolutions. Dispersion also refers to the random relocation of individual grains due to collisions between adjacent particles and can take hundreds to thousands of revolutions to act. Thus particles cross a plane separating the two arms of the V-blender (or an equivalent symmetry plane in many other blender geometries) only as a result of occasional collisional happenstances and not as a result of an overall mean flow. Various stratagems, including the use of baffles, asymmetric cross-flow designs (referred to earlier), irregular rotation protocols, or axial rocking, have been introduced to mitigate this limitation. Notwithstanding these improvements, dispersion is the rate-limiting mechanism for mixing, and there is much potential for improvement of dispersive mixing.

Although convection is typically orders of magnitude more rapid than dispersion, as a practical matter the relative contribution of each mechanism to blending is strongly influenced by the initial distribution of species in the mixer. Thus ingredients loaded in horizontal layers (as in Fig. 7) can be mixed relatively rapidly, while ingredients layered side by side (either intentionally (as in Fig. 8) or inadvertently (as a result of careless loading of a tumbler) will typically mix enormously more slowly.

Fig. 8 Dispersive mixing is slow across the symmetry plane of a blender, here a tote design. After 10 revolutions, a front view reveals clear evidence of the initial left-right distribution of identical but colored spheres in this particle-dynamic simulation.

To visualize this effect, in Fig. 8 is shown the dispersive mixing of 8000 identical but colored grains loaded side by side, here in a tote blender. With each successive revolution, only a few particles cross the interface separating the two symmetric halves of the tumbler, and as a result, after 10 revolutions the original particle ordering is still unmistakable. Systematic assays obtained from experiments of blending of realistic pharmaceutical excipients and actives confirm that imperfectly loaded blends retain any initial asymmetry for many hundreds of tumbler revolutions.

Shear

A final class of mechanisms of granular and powder mixing is grouped under the category of shear. This includes a host of very different mechanisms that act in a shearing layer (cf. Fig. 2) or in a high-shear region as produced by an intensifier or related device. Grains rearrange during shearing and so disperse across a shear layer. In addition, large or irregular grains tend to be expelled from regions of high shear through a mechanism known in research on suspensions as “shear-induced migration.” Finally, arrangements of adjacent grains become distorted through the influence of external strain. This is the most classic form of shear mixing, which itself admits several distinct subcategories.

First, there is the simple effect of shear on deforming a granular bed. In simple tumblers, this can manifest itself in a nearly continuous distribution of strain, resulting in regular and predictable mixing behavior such as is displayed in Fig. 4c. This figure was obtained using freely flowing grains, of mean size nearly 1 mm.

Second, a granular bed consisting of weakly cohesive materials (e.g., nontacky grains in the size range 50–300 μm) exhibits stick-slip motion so that flow becomes intermittent rather than continuous. This is a situation of practical importance because pharmaceutical blends, for example, use particles across a broad range of sizes and materials. As the size of grains diminishes or as interparticle cohesion grows, stick-slip flow transforms mixing interfaces from smooth, regular, patterns as shown in Fig. 9 (500- or 700- μm cases) to a complex, irregular pattern, shown in Fig. 9 (300- or 100- μm cases). In simple geometries, this response to shear can be accurately modeled: if we assume that the flowing surface of a bed periodically sticks and slips, then the mechanism displayed in Fig. 4a can be embellished by allowing the shear band between flowing layer and bed to deform periodically (2). This produces patterns of mixing between initially separated but identical grains that are substantially similar to experiment, as shown at the bottom of Fig. 9.

Fig. 9 Mixing patterns after 1 revolution in drum tumblers loaded with identical (except for color) grains in four experiments using successively finer grains, as well as in a model simulation of idealized stick-slip flow. At 700 and 500 μm , the mixing interface remains smooth and regular, while below about 300 μm , it becomes variegated due to intermittent slipping of the cascade. Each experimental snapshot shows a view from the interior of a blend using the solidification technique described in the section on Solidification in this article, and all cases began with light grains to the left of center and dark grains to the right.

This is important for blending because in smooth, regular flow, adjacent particles remain nearby for long periods of time, while in intermittent, stick-slip flow, particles can rapidly relocate across the blender. It is not difficult to show that periodic sticking and slipping results in an exponentially rapid growth of interfaces between separated regions of grains.

Third, for particles smaller than about 100 μm , cohesive forces (believed to be due to van der Waals interactions for intimate contacts, and to surface tension of adsorbed water layers for lubricated contacts) between particles becomes comparable to particle weights, and small particles can stick to one another in relatively rigid aggregates. Unless such aggregates are destroyed, the system will behave as if it had an effective particle size much larger than the primary particle size.

For strongly cohesive materials, it is typically necessary to fragment agglomerates through the introduction of high shear, “intensification,” devices such as impellers or mills that energetically deform grains on the finest scale. Intensification is commonly performed in an early preblending stage using a fraction of the total desired excipient to avoid overblending the final product. Results of intensification are discussed in the section on Assays.

DEMIXING

Processing the blends of dissimilar grains almost invariably promotes demixing, also referred to as segregation, characterized by the spontaneous emergence of regions of nonuniform composition. Segregation due to differences in particle size in a blend has drawn the

greatest attention in the literature, including studies of fluidized beds, chutes, hoppers, vibrated beds, and tumbling blender. Segregation due to particle density, shape, and triboelectric order have also been recorded. As a practical matter, segregation manifests itself in granular mixing that characteristically improves over a brief period (while convection generates large scale mixing) and then degrades, often dramatically (as slower segregational fluxes take over). Demixing should not be confused with the phenomenon of overblending, which is also frequently encountered in blending applications. Overblending is associated with physical degradation of material properties, as occurs for example when a waxy lubricant is excessively deformed causing it to coat pharmaceutical grains and reduce their bioavailability, or when coated granules are damaged through abrasion or fracture.

At the present time, mechanisms for segregation even in the simple tumbling drum remain obscure, and work on more complex and industrially common blender geometries is extremely limited. Three distinct types of demixing are moderately well characterized in tumblers. They are radial demixing, axial demixing, and competitive patterned demixing. We describe each of these in turn.

Radial Demixing

Segregation typically proceeds in two stages. First, large grains rapidly segregate radially, producing a central core of fine grains surrounded by larger grains, identified in Fig. 10 for a simple drum tumbler. Unlike the core seen in overfilled tumblers (Fig. 3c), this core appears at fill levels under 50% and is exclusively associated with migration of fine grains toward the center of an overturning blend. Radial segregation is seen in both quasi-2D and fully 3D blenders of various geometries. In simpler 3D geometries, such as the drum, double-cone or tote, the core is nearly always apparent when blending significantly dissimilar grains, while in more complicated geometries such as the V-blender or slant-cone the core becomes significantly distorted and may only be conspicuous for higher fill levels or in certain (e.g., upright) orientations of the blender. Even in the simplest case of the drum tumbler, however, the location and dynamics of the core remain somewhat enigmatic: as shown in Fig. 10, the core is actually located upstream of the geometric center of the granular cascade.

The core appears to form as a result of two cooperative influences. First, smaller grains percolate through the flowing layer to occupy successively lower strata each time the bed overturns. Second, once a sufficient volume of smaller grains has accumulated, the larger grains tend to roll increasingly freely over the (comparatively smooth)

Fig. 10 Typical segregation pattern seen between fine (dark) and coarse (light) grains in small transparent drum tumbler. A core of fines extends along the entire length of the tumbler, connecting the bands that emerge at the surface in a single bulging tube. The coarse grains are constrained to flow within the confines defined by this tube. This constraint is important for understanding mechanisms of demixing in more complex geometries, as described in the section on Competitive Patterned Demixing in this article.

substrate of smaller grains. This higher speed surface flow reinforces the segregated state by expelling remaining slower small grains. These mechanisms are very robust, and cores are almost invariably found in tumbling of freely flowing grains with diameter ratios between about 1:1.5 and 1:7. As the diameter ratio approaches unity, the core becomes more diffused, while as the diameter ratio grows sufficiently large, fine grains can percolate increasingly freely through a matrix of larger grains or, if sufficiently fine, can coat the larger species.

Axial Demixing

A second stage of segregation occurs in drum tumblers as grains in the core migrate along the tumbling axis. Numerical and experimental investigations have attributed this migration to conflicting causes, e.g., a secondary flow within the core leading to a bulging of the core toward the surface versus different angles of repose of fine, mixed, and coarse grains. Whatever the ultimate cause, the result of this axial migration is the formation of a series of bands as shown in Fig. 10. In this final state, two pure phases of material are formed, divided by sharp boundaries with very little intermixing.

Competitive Patterned Demixing

In more complex, and more common, tumbler geometries, several distinct segregation patterns have been observed. These patterns are believed to arise from a competition between surface segregation of coarse grains flowing over

Fig. 11 Axial segregation in top views of double-cone blender from (a) experiment and (b) particle-dynamic simulation using large (light) and small (dark) spherical grains. Similar patterns are seen in other tumbler designs, for example in the V-blender in (c) experiment and (d) simulation.

a radially segregated core of fine grains and interactions with the boundaries of the tumbler. Despite significant differences between common blender geometries, there is substantial commonality in the ultimate patterns seen. For example, mixing of large, light-gray and small, dark-gray grains in a double-cone and a V-blender generates similar patterns in both experiments and particle-dynamic simulations, as shown in Fig. 11.

As parameters such as fill level, tumbler speed, and concentrations of the different particle species are varied, the patterns observed though change significantly. Importantly, there appear to be a few dominant and recurring patterns that are seen both in experiments and in simulations in all blender geometries. Notably at high fill levels and tumbling speeds, the “left-right state” shown in Fig. 1 appears to dominate. This pattern and two other common variants are shown at the top of Fig. 12 in top views of the surface of a double-cone blender. Each of these patterns appears reproducibly and spontaneously whenever different size grains are tumbled in any of several blender geometries. Simulations shown beneath the experimental figures in Fig. 12 use a continuum model in which large particles are convected on the surface of an idealized convex bed of smaller grains. Container geometry is included by assuming that large particles rebound specularly when they reach the downstream boundary of the idealized blender. Correspondence

Fig. 12 Three common segregation patterns between large (light) and small (dark) grains seen in top views of double-cone blender. Top: experimental snapshots. Bottom: simplified continuum simulations.

between experimental data and this simulation indicates that ongoing improvements in modeling show promise for unveiling the underlying mechanisms of demixing and permitting eventual accurate modeling of practical granular processing systems.

Scaling

An ultimate goal of granular research is to enable processing to be scaled up from bench to pilot to full-scale operations. Scale-up methods are well developed in other, (e.g., fluid) operations, but remain a distant objective in granular systems. Several alternative scale-up approaches have been suggested. For example, the natural dimensionless group associated with granular flow at a known speed, v , down a specified height incline, h , under gravity, g , is the Froude number, defined to be the ratio of kinetic to potential energies: $Fr = v^2/gh$. Experimental analysis reveals, however, that neither mixing nor segregation scale with Fr . Reasons for this are several: the competing mixing mechanisms of convection, diffusion, and shear each act on different characteristic time scales, and their interactions are therefore complex in the extreme. Additionally grains accelerate down a cascading surface, and therefore the resulting behavior changes qualitatively depending on whether they do or do not reach an asymptotic speed in the cascade (for example, compare Figs. 4c and 5). These and other influences make first-principles analysis of granular scale-up problematic.

Nevertheless, reproducible empirical scaling relations do appear to be attainable for specific blenders. As an example, in the drum blender it has been determined that dynamically similar convective flow occurs provided that

$R \cdot \Omega^{2/3}$ is held constant for lower tumbling speeds (where particles reach a terminal speed in the cascading layer) and provided that $R \cdot \Omega^{1/2}$ is held fixed for higher tumbling speeds (where particles do not reach a terminal speed), where R is the drum radius and Ω is the tumbler rotation speed. Likewise the demixing patterns shown in Figs. 1, 11 and 12 are found at all blender scales, and dynamical similarity relations have been obtained for transitions between these patterns. These encouraging findings indicate that scaling of a particular granular blending process in a specified geometry may be possible, but that scaling relations can be expected to vary quantitatively as process parameters (e.g., material properties, fill levels, tumbler geometries, etc.) are changed. As in any rapidly evolving field, the current state of understanding is not yet fully adequate for practical needs, but research trends show promise for the intermediate and longer terms.

MIXING MEASURES

A prerequisite to meaningful evaluation and interpretation of mixing is the use and understanding of a reliable measure of mixing. Though this concept may seem straightforward, some care needs to be exercised in its implementation. Any mixing measure is obtained by first evaluating a relevant quantity, typically concentration, in specified sample regions. Ideally, in order for the samples to be representative, they should be taken uniformly from a flowing stream that is itself uniform both in space and time. In tumblers, this is not practical, and very often sampling consists of extracting small aliquots of grains from a static bed. We discuss techniques, and limitations, of extracting such aliquots shortly, but first it is worthwhile to review what one would do if provided with complete access to concentration data throughout a granular bed. Such an idealized scenario is sketched in Fig. 13, where we display sequential snapshots of a 2D bed. Suppose we can subdivide the blender into identical boxes—elements of area in 2D, elements of volume in 3D. In each box, let us define a concentration, C_a , of a species of interest. Thus C_a might range from 0 in the black regions of Fig. 13, to 1 in the light-gray regions.

Data Interpretation

The first thing to notice is that not all boxes are completely occupied by grains, and boxes near the periphery of the bed can bias results strongly. For example, in the leftmost snapshot, partially filled boxes consist of anomalously high concentrations C_a , and an unweighted evaluation of

Fig. 13 (a) Subdivision of blend into sampling regions. By determining concentrations, C_a , of interest in each region, one can compute relevant statistics. (b) and (c) as time progresses, concentrations approach a mean value with standard error that diminishes as the number of sampled regions increases.

concentrations in all boxes would yield a mean concentration, for this particular case, of 60% light-gray grains. This is clearly wrong, and can be corrected either by reducing the box size (hence diminishing the fraction of boxes containing a boundary of the bed) and excluding boundary boxes or, preferably, by weighting each box based on its fractional fill level.

A second issue is that there is necessarily a trade-off between precision and resolution. That is, if the box sizes are reduced, one obtains more boxes and hence more values of C_a , and consequently any mixing measure will in principle have a lower standard error. On the other hand, this reduction has an obvious limit as the box size approaches the grain size, at which point any blend will statistically appear to be unmixed (because each box can only take on one of the two values, $C_a = 0$ or $C_a = 1$). In practice, a happy medium delivering both suitably low standard error and an adequate sample size^b is easily achieved; nevertheless it is important to understand what it is that one is seeking to obtain before deciding on a sampling protocol.

A third issue is illustrated in Fig. 14, where we plot three schematic mixing states, each containing the same fraction of light and dark regions. Plainly the leftmost state is fully segregated, but most simple measures would provide the same evaluation of mixedness for the two other states. Moreover, the rightmost schematic represents a common outcome of shearing flows (cf. striated state in Fig. 9). For this reason, it may be desirable to customize one's mixing measure to accurately reflect the desired endpoint of measurement, and correspondingly innumerable different mixing measures have appeared in the literature. These many different measures unfortunately do little to advance the comprehensive understanding of granular blending or to permit comparisons between different data sources, and it is

^bTo compute a lower bound on box size, one typically assumes Poissonian statistics for the presence or absence of particles within a given box, so that uncertainties in a box containing n particles go as.

Fig. 14 Illustration of the importance of rational data interpretation. The state (b) intuitively looks well mixed, but has the same number of black and white boxes as states (a) and (c). Evidently a larger box size is required to make meaningful mixing measurements. States (b) and (c) have very different structures, but produce similar measures of mixing using common statistics. For this reason, many customized mixing measures have evolved in the literature.

consequently preferable, where feasible, to use a single set of mixing measures as suggested in the next section.

Intensity of Segregation

One of the most useful measures of mixedness is the intensity of segregation. This is little more than a normalized variance of concentration measurements. Intrinsic to the use of intensity of segregation, therefore, is the presumption that the mixing distribution is, at least to a first approximation, Gaussian. This raises two issues: first, it is not clear that granular mixing tends toward a Gaussian state, and second, in many practical applications a Gaussian is not the desired outcome. Indeed, in pharmaceutical processing, if a blend were Gaussian rather than uniform, then the unavoidable presence of exponential tails on a Gaussian distribution would guarantee that some small fraction of tablets made from the blend would be beyond any therapeutic range that one could specify. Fortunately, granular flows seem to scatter grains more uniformly than a simple Gaussian would predict, although the details and mechanisms for this behavior are not yet well understood.

With these caveats in mind, a definition of the intensity of segregation is:

$$I = \frac{\sigma^2 - \sigma_r^2}{\sigma_o^2 - \sigma_r^2}, \quad (1)$$

where σ^2 is the variance of sampled data, σ_r^2 is the variance of the same number of randomly chosen concentration data, and σ_o^2 is the variance of an initial, typically fully segregated, state, again consisting of the same number of data points. Several forms of I appear in the literature; this form is useful because it is normalized so that $I = 1$ and $I = 0$ correspond to completely segregated and randomly mixed states, respectively.

Two other mixing measures of importance to pharmaceutical processing are, first, the relative standard deviation (RSD), defined to be:

$$\text{RSD} = \frac{\sigma}{\langle C_a \rangle} \quad (2)$$

where σ is the standard deviation and C_a is the mean concentration over all samples taken, and the mixing rate, k . The mixing rate is defined according to the relation:

$$I = I_o e^{-kt} \quad (3)$$

where I_o is an initial intensity and t is time. Many, though not all, mixing mechanisms produce an exponential approach to uniformity as presupposed by Equation (3). Deviations from Equation (3) are discussed in the next Section; for now, if we assume that the intensity of segregation decays according to Equation (3), we can extract a mixing rate from any given experiment and thereby evaluate and compare mixing efficiencies of different blenders, of blenders operated under different conditions, and of effects of changes in material or other properties of interest.

Examples

Mixing rates

To examine the behavior of mixing measures, it is useful to begin by considering systems free of experimental uncertainties. Particle dynamic simulations such as those discussed in the sections on Mixing mechanism in Three Dimensional Tumblers; and Demixing, represent such ideal systems: the presence and locations of all particles are known and are free of sampling errors (discussed in the section on Sampling Techniques).

The simplest of these simulations from the point of view of mixing measurement is the double-cone. Raw variances taken from volume elements initially separated axially in the blender are shown in Fig. 15a. The variances are color coded according to the initial locations sketched in the inset. Evidently, after the first or second revolution of the blender, variances decay nearly exponentially (i.e., linearly on this semi-log plot). Mixing is slowest, however, between particles initially near the axial center of the blender (light gray in Fig. 15a). This is to be expected because, as commented earlier, the rate limiting mixing process is dispersion across the symmetry plane of the blender, or looked at another way, grains starting further from the symmetry plane experience a secondary axial convective flow, that grains closer to this plane do not.

Fig. 15 Variance of concentrations of identical color-coded grains from particle-dynamic simulations of (a) a double-cone and (b) a V-blender. Notice that the smooth flow in the double-cone is reflected in a smooth, asymptotically exponential, reduction in variance with time, while the sloshing flow in the V-blender (cf. Fig. 7) produces periodic undulations in mixing response.

It is instructive to compare this simulation with its counterpart in the V-blender, shown in Fig. 15b, where mixing is much more irregular. This irregularity has been traced to periodic sloshing of grains to and from the arms of the blender. Again there is a barrier to mixing across the symmetry plane of the tumbler, but comparison of the scales of Figs. 15a and b reveals that the sloshing process accelerates mixing significantly. Thus as one would expect, the smooth flow seen in the double-cone is manifested in a smooth decay in variance shown in Fig. 15a and modeled by Equation (3), while the periodic sloshing of grains in the V-blender is poorly fit by such a simple relation. For all tumblers, it is notable that mixing evolves with each successive tumbler rotation and not with elapsed time, and all studies indicate that tumbler rotation rate (within a fixed regime) is nearly inconsequential.

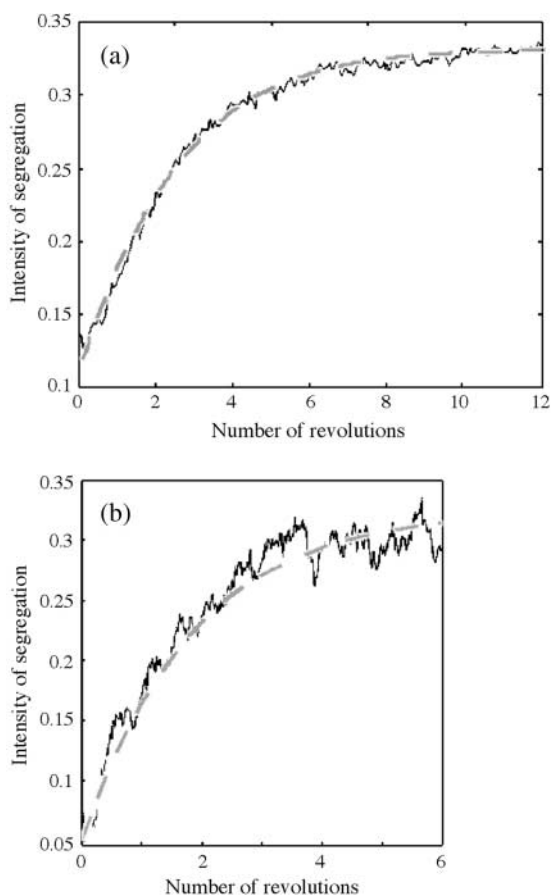

Fig. 16 Evaluation of segregation between different size particles in particle dynamic simulations in (a) double-cone and (b) V-blender.

Segregation rates

As its name suggests, the intensity of segregation is especially useful for analyzing segregating mixtures. For example, rather than evaluating I in a simulation of identical particles, as shown in Fig. 15, if we evaluate I for a simulation of the segregating mixture in the double-cone shown in Fig. 11b, we obtain the plot shown in Fig. 16a. Here the blend starts from an artificially mixed state, $I \ll 1$, and approaches an asymptotically segregated state, $I \cong 0.3$. The solid data points are obtained by dividing the total occupied volume into separate boxes and calculating the number of small grains within each box. The dashed gray curve is an exponential approach to an asymptote included for comparison, which indicates that segregation, as well as mixing, in simple geometry tumblers obeys a simple exponential relation. For more complex tumbler geometries, segregation approximately follows an exponential approach to an asymptotic

segregated state, but is more erratic, as shown in Fig. 16b for the V-blender.

SAMPLING TECHNIQUES

Thieves

In practical blending processes, one cannot obtain arbitrary quantities of pristine data as one can using particle-dynamic simulations, and one must settle for sampling a static bed, as mentioned previously. In such a case, it is especially important to understand sampling limitations and systematic biases. A common means of obtaining samples in a tumbler is by the use of a scoop or thief sampler. These samplers are inserted into the bed and extract samples from its interior. In such an application, it is necessary to obtain a representative spatial distribution of samples throughout the bed, and for this purpose it is recommended that one build a jig above the tumbler opening into which one can insert samplers at fixed locations in the plane of the opening and to specified depths perpendicular to the plane.

The behaviors of two popular types of thief samplers are shown in Figs. 17 and 18. In Fig. 17 is shown the result of inserting a “side-sampling” thief, consisting of a tube with a slot in its side that can be opened to allow grains to flow into a cavity and closed to extract the sample. In the photograph of Fig. 17a, an interior section of a solidified bed (see section on Solidification) of light gray 200- μm and dark 60- μm grains is shown. The grains are initially layered, and from this snapshot it is clear that the act of inserting the thief causes grains to be entrained along the insertion route. This entrainment causes local particle rearrangements that typically result in the bed appearing to be anomalously well mixed. It is also significant that side-sampling thieves rely on particle flow into the sampling cavity to obtain grains, and consequently freely-flowing or smaller grains can penetrate the sampling slot more readily than cohesive or larger grains. These conclusions are borne out in quantitative tests: in Fig. 17b, we plot the fraction of smaller beads in samples obtained using a side-sampling thief in separate experiments in which 60- μm grains are initially arranged in a single thick layer over a bed of 200- μm grains. Evidently the thief obtains samples almost entirely consisting of the smaller species, irrespective of the genuine concentration originally in the sampling location.

The problem that side-sampling probes do not allow larger or more cohesive grains to enter the sampling cavity can be mitigated through the use of “end-sampling” thieves such as the one shown in Fig. 18. In these thieves, the sampling tube is inserted to a desired depth in the bed, an aperture at the distal end of the probe is opened, and then

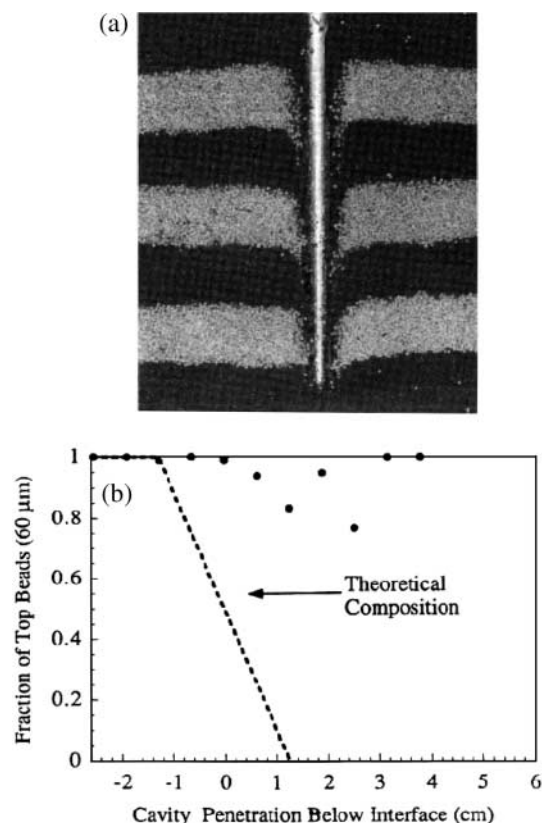

Fig. 17 Systematic sampling errors introduced by a side-sampling thief. (a) Initially layered configuration of large (light) and small (dark) grains are noticeably disturbed as this thief entrains grains during insertion. (b) This type of thief relies on free flow of grains to fill a cavity when a slot is opened in the side of the sampling tube. Consequently, fine and freely flowing grains are overrepresented by this probe, and fine grains are transported to regions where they were not originally placed.

the probe is pushed deeper into the bed and the aperture is closed again to allow extraction of the sample. Because grains are actively forced into the cavity, rather than passively flowing into it as in side-sampling thieves, this device is relatively free of differential sampling problems as can be caused by differences in particle flowability. However, as shown in Fig. 18a, these devices are typically bulky and consequently entrain considerable material during their insertion. The resulting sample concentration measurements (Fig. 18b) are therefore improved over those of the side-sampling thief, but remain very inaccurate and the data consistently overestimate a blend's mixedness.

Core Sampling

An alternative that is nearly free of either flow (e.g., Fig. 17b) or entrainment (e.g., Fig. 17a) anomalies is the

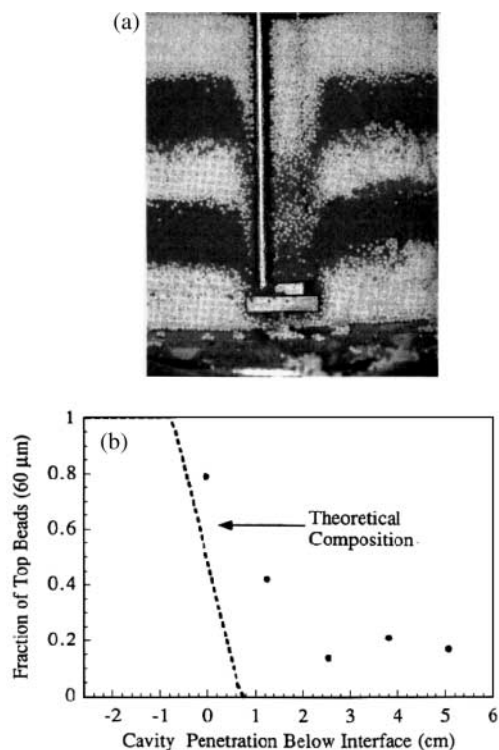

Fig. 18 Sampling errors introduced by an end-sampling thief differ from those of a side-sampling thief, but persist nonetheless. In this type of thief, a window is opened at the bottom of the sampling tube and grains are forced into a cavity by further insertion of the thief. This eliminates the bias toward grains that passively fill a cavity more easily than others, but on the other hand, (a) these thieves entrain more grains during insertion and (b) their performance again suffers from substantial systematic error.

“core-sampler.” This sampler extracts an entire contiguous core of grains throughout the depth of insertion. At its simplest, the probe consists of a thin walled tube that is inserted into a granular bed, together with a mechanized extrusion apparatus to permit samples to be extracted in a last-in, first-out manner after the tube has been removed from the bed. In the case of freely-flowing grains, which could otherwise flow out of the tube, the device is embellished by incorporating an end-cap that can be opened during insertion and then closed during extraction. Unlike the end-sampling thief, the end-cap mechanism here is internal to the sampling tube, and an entire core is extruded from the bed. The behavior of this device is demonstrated in Fig. 19. Using the end-cap (shown closed in Fig. 19a), the concentration data obtained compare favorably with other methods, as shown in Fig. 19b. Importantly, in the core sampler the core extends through the depth of the sampling tube and so sample sizes are large. Random uncertainties

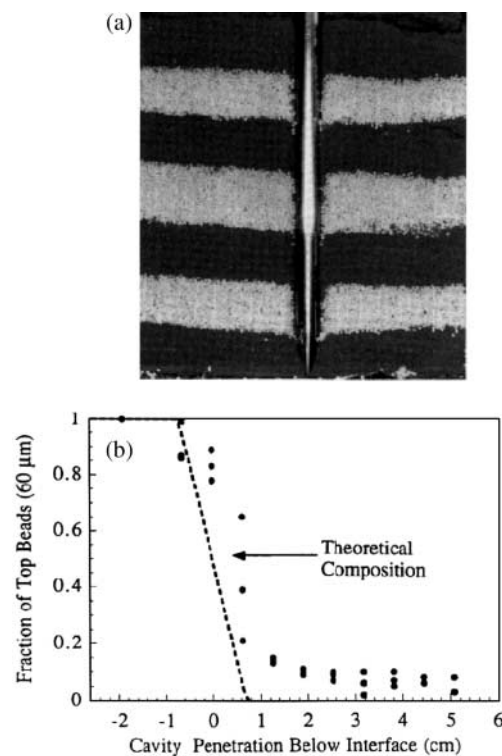

Fig. 19 Core sampler with end-cap can be used for freely-flowing (e.g., granulated) materials that would escape from the sampling tube during removal from the bed without the end-cap. (a) Very little entrainment is visible after insertion, and (b) systematic errors are reduced.

are therefore small and corrections for systematic errors that remain can be predictably made.

Without the end-cap, agreement between experiment and theory is further improved. In Fig. 20 we display core sampling results for three different inner diameter sampling tubes using a two-layer bed of common pharmaceutical excipient powders: microcrystalline cellulose and lactose. For all sampler diameters, the experimental data are indistinguishable from ideal expected concentrations. In practice, we note that it is important that the walls of the sampling tubes be polished (to prevent excessive entrainment and difficulty filling the tube during insertion) and that a well-regulated extrusion device be employed.

Assays

Once samples have been obtained, one can use a variety of available chemical, optical, spectroscopic, chromatographic, or other assays to determine concentrations of interest. For example, data in Fig. 20 were obtained using a calibrated densitometric technique in which one

Fig. 20 Non-freely-flowing, powdered material can be extracted from a blend using a core sampler with an open end. In this case, measurement errors are virtually undetectable, here in a sampling experiment using a thick layer of microcrystalline cellulose above a bed of lactose.

of the two species was colored in advance; identical results have been obtained using other assay techniques, e.g., reflection near-infrared spectroscopy used to evaluate distributions of magnesium stearate (a common pharmaceutical lubricant). One particularly useful technique for evaluating the effectiveness of tumbler design or process modifications involves the use of conductivity assays. For this technique, standard nonionic excipients are blended with mock-actives consisting of simple soluble salts (e.g., KCl or NaCl) granulated in the size of interest. Samples extracted from the interior of the blend using core-samplers (inserted at controlled locations using a jig as described previously) are then extruded in fixed weight aliquots and dissolved in a known quantity of solvent (typically just deionized water). The concentration of the solution is then measured using commercially available probes, and by comparing concentration data with calibration curves obtained separately, one can rapidly and accurately establish mixing statistics of the mock-active as a functions of operational parameters of interest.

As an example, we have mentioned that it is typically necessary to fragment cohesive agglomerates through the use of an intensifier bar (a high speed impeller) or similar device. To investigate the effectiveness of intensification during preblending, in Fig. 21 we show plots of RSD of mock active vs. blending time in a V-blender with and without intensification. Each data point is obtained from a separate experiment in which the blender is loaded in predefined layers and then tumbled for the specified time, after which multiple samples are taken (again always from the same locations in the bed) and assayed. Because the samples are taken using entire intact cores, large numbers of data are obtained throughout the depth of the bed.

Fig. 21 Mixing rates in a V-blender tumbled at 24 rpm with and without shear induced by a high speed intensifier bar.

Typically nine cores are taken, distributed uniformly in a grid around the blender opening; since the V-blender has two arms, in this set of experiments five cores were taken through openings at the end of each arm.

By solidifying an entire blend, one can obtain data in enormous quantities and in exceedingly high detail. For example, in Fig. 23, we show the interior of a blend in a double-cone solidified using a methacrylate solution and then sliced open through the tumbler symmetry plane. Here $\sim 90\text{-}\mu\text{m}$ grains have been blended beginning with a segregated initial state, and the mixing structure, characteristic of stick-slip flow (described earlier), can be resolved down to the size of the grains themselves.

This type of sampling protocol permits the quantification of mixing under a variety of different conditions. As we have mentioned, because core sampling provides large quantities of bed material in a reproducible manner, one can assay some of the samples and retain others for later analysis—e.g., to perform dissolution or bioavailability tests or for archival purposes.

Solidification

Core sampling combined with calibrated assaying techniques represents the best available technology for quantification of mixing of industrial scale blenders. Other techniques are available, however, for laboratory scale studies. The gold standard for these is the solidification technique, described here. To solidify a granular bed, one performs a mixing experiment using colored or otherwise distinguishable grains and infiltrates the blend with a polymeric solution such as methacrylate copolymer, low viscosity epoxy, or heated gelatin. The polymer is allowed to set, and the solidified monolith is

sliced open using a saw (for large samples solidified with methacrylate or epoxy) or a knife (for samples set in comparatively soft gelatin) to reveal internal mixing patterns. Separate experiments using structured (e.g. intentionally layered) blends confirm that the blend is not disturbed by infiltration provided that the infiltration is carried out slowly and from one end of the tumbler to the other (so as to avoid trapping bubbles). This technique is appropriate only for laboratory scale apparatus, in which setting times are short and it is feasible to handle and slice the entire frozen blend. Additionally, the technique typically involves sacrificing the blending vessel (which is obviously not always practical), although blends solidified in gelatin can be released from the blender by heating it from outside.

Typical results are shown in Fig. 22 using a segregating mixture of fine, dark, and coarse, light, grains in a drum tumbler solidified using gelatin. The slices displayed show clear evidence both of radial and axial segregation. These slices incidentally also reveal an evident shortcoming of attempting to visualize mixing only from the outside of the blend. This has been done many times in the literature, but without validating the results by examining the interior of the bed, such studies can be grossly misleading, as the differences between the exterior and interior slices shown in Fig. 22 illustrate.

Other Techniques

Other, more technologically involved, techniques have also been developed for visualizing the interior of granular beds. These include:

- Diffusing wave spectroscopy, used to measure statistics of fluctuations in relatively thin, Hele-Shaw configurations
- Positron emission tomography, in which a single radioactive grain is tracked during flow within a granular bed using an array of external photomultipliers
- Magnetic resonance imaging, in which magnetic moments of hydrogenated grains are aligned in structured configurations (e.g., stripes) and these structures are tracked for short periods of time
- X-ray tomography, in which a population of radio-opaque grains are tracked in a flow of interest.

These techniques are typically expensive and cumbersome to implement; nevertheless they reveal flows within an optically opaque bed and provide valuable information not attainable otherwise. For example, in Fig. 24, we display results of x-ray tomography experiments that show the evolution of the interior mixing structure within a double-cone blender using molybdenum-doped tracer particles (dark in Fig. 24). These experiments represent a

Fig. 22 Internal and external slices obtained by solidifying a blend, here of coarse (light) and fine (dark) grains in a drum tumbler. Segregation is evident, and the difference between internal and external slices highlights the importance of not relying on external appearances of tumbled blends.

scaled-up version of the solidification data shown in Fig. 23: the capacity is 8 times larger (~ 4.8 L vs. 0.6 L), and the particle diameter is 18 times larger (~ 1600 vs. 90 μm). Data of this kind reveal a complexity in flow and mixing evolution that simultaneously represents the cause

Fig. 23 High-resolution data are obtainable by solidifying and slicing an entire blend, here of identical but colored ~ 90 - μm grains in a double-cone blender.

Fig. 24 X-ray tomographic time series of blending of radio-opaque grains in double-cone blender is representative of several new techniques available for on-line and in situ assays of blending mechanisms.

of historical difficulty in understanding the subject and the opportunity for future developments.

ORPHAN DRUGS

Carolyn H. Asbury

University of Pennsylvania, Philadelphia, Pennsylvania, U.S.A.

INTRODUCTION

As drug development costs began to rise in the late 1960s and 1970s with new Food and Drug Administration (FDA) requirements for demonstrating relative safety and efficacy, manufacturers of drugs, biologicals, and diagnostic agents faced a dilemma. How could they consider developing drugs that were important medically but not likely to be profitable? Drugs for diseases and conditions that were rare in the United States were one of several—and the most visible—of such drug types. Rarity meant few patients would be available to participate in clinical trials of safety and efficacy under the sponsor's Investigational Exemption of a New Drug (IND) application. Slow patient recruitment into trials increased development time, with the 17-year patent-protection clock ticking. And once the pharmaceutical sponsor received approval for the New Drug Application (NDA) required for interstate marketing, there would be few customers. This generally translated into a low return on investment (ROI). Moreover, the time devoted to testing and gaining approval for a drug for a rare disease was an opportunity cost. Manufacturers would otherwise have devoted the time and resources to products with more favorable market returns.

Six other drug categories were of limited commercial interest. They included products for (1):

1. Chronic diseases, requiring extended testing phases to assess long-term effects, using up critical patent-protection time;
2. Single administration, such as vaccines, requiring separate production facilities, used by many but on a one-time basis, and carrying high liability risks; and diagnostic agents that had relatively low sales volume;
3. Women of childbearing age, presenting unparalleled liability risks;
4. Children and the elderly, both of whom were excluded from clinical testing at the time. Children presented high liability risks and could be difficult to enroll in clinical trials. Elderly people, who often had multiple conditions, were excluded from trials by the FDA because the multiple conditions and drugs used to treat them would confound trial results. (Once a drug was

marketed, physicians could prescribe it for these two populations. However, optimal dosing had not been determined, and likely drug interactions in elderly patients had not been identified);

5. Diseases, rare or common, for which the intended drugs were not patentable including shelf chemicals, drugs known to exist, natural chemicals, and drugs for which the patent had expired;
6. Substance abuse or relapse prevention, intended for a population considered to be a high liability risk, uncooperative with treatment trials, and requiring extensive records once marketed; and
7. Developing countries, with the related problems of distributing and paying for products.

Observing that certain drugs could be in common use but were not potentially profitable enough to invite commercial introduction, Provost referred to them in the *American Journal of Hospital Pharmacy* in 1968 as homeless or “orphan” drugs (2). This chapter focuses on orphan drugs for rare diseases. It provides background on the issues and on attempts to deal with them—a description of the Orphan Drug Law, enacted in 1983, to address these issues—and an accounting of progress and problems to date emanating from the law.

BACKGROUND

The 1938 Food, Drug and Cosmetics Act and the 1962 Kefauver-Harris Amendments to it substantially altered drug development in this country. They strengthened the safety and efficacy determinations of drugs, but at cost, one of which was industry disinterest in drugs for rare diseases. The 1938 law required proof of safety after diethylene glycol, used as a sulfanilamide vehicle was found to form lethal quantities of oxalic acid in the body. This resulted in 100 fatalities, mostly children (3). The law required manufacturers to provide evidence that the drugs were relatively safe. For the FDA to keep a drug off the market, however, the onus was on the *agency* to prove that the drug was not safe. The thalidomide disaster changed that situation. Tragic birth defects were reported

in infants born to women in Europe and Canada who had taken the drug while pregnant. At the time the news broke, Congress was working on amendments to the 1938 law that required sponsors to provide proof of drug efficacy before receiving market approval. The thalidomide catastrophe propelled Congress to require sponsors also to show proof of safety. To implement these two requirements, the FDA created the IND process requiring sponsors to test for and establish relative safety before embarking on clinical trials to determine drug efficacy. The FDA set up the NDA approval process for ruling on safety and efficacy before the drug could be marketed interstate (4).

An essential interplay developed between patent protection and regulatory requirements. Patent protection became essential for emerging products developed by research-intensive, vertically integrated firms that looked to a few major market winners to survive in this era of increased development costs (5). Patent time used in the IND and NDA premarket stages reduced the time remaining for manufacturers to protect their products, once marketed, against less costly generic drug competition. Drug development also became more expensive. Development costs in the late 1960s and early 1970s, before the FDA amendments became operationally implemented, were estimated to range from a low of \$2.7 million to a high of \$16.9 million per new chemical entity (NCE) (6, 7). By the late 1970s, the estimate had risen to \$54 million (8). Since then, estimates have continued to leap upward: \$124 million in the late 1980s, \$231 million in 1991, and \$500 million today (9, 10).

By the late 1960s and early 1970s, market winners generated most of a company's profits and also helped encourage brand loyalties by prescribing physicians. Other drugs needed to at least break even. Although not blockbusters, these drugs generally were for large markets. Drugs for rare diseases usually did not break even and became therapeutic orphans. They became wards of government and university-sponsored development efforts.

Cancer treatment drugs were among the first wards of government. Even before the 1962 amendments to the Food, Drug and Cosmetics Act, the federal government had developed and maintained a role in stimulating the development of cancer drug treatment that was not being addressed by industry. The National Cancer Institute (NCI) created the Cancer Chemotherapy Program in 1955 with a \$5 million Congressional authorization. Congress decided that the NCI should take on the challenge. Impressed with industry's spectacular antibiotics development, Congress recognized that a low ROI was precluding industry's interest in exploiting the early successes in antitumor drugs (antifol aminopterin for acute childhood leukemia and

methotrexate for uterine choriocarcinoma). Beginning as a small grant-oriented program to develop antileukemia agents, the program was based on the use of transplantable tumors in syngeneic rodents as a system for testing new drugs. After the NCI drafted an agreement allowing for the trade secret status of data, industry submitted compounds for screening of bioactivity. Within three years, the Cancer Chemotherapy Program had grown into a \$35 million industrial contract effort. After a few missteps, when the FDA would not accept the cancer-funded research results as provided, the FDA and NCI developed a clear understanding of how data needed to be provided. From that point until at least the early 1980s, the NCI was involved in the development and/or clinical testing of every antineoplastic drug available in the United States (11–13).

In 1966, the National Institute of Neurological and Communicative Disorders and Stroke, as it was then named, established the Antiepileptic Drug Development Program to develop clinical trial methodologies and then to conduct clinical trials of antiepileptic agents already available in other countries. The program later developed a screening program similar to that of the NCI. The Institute filed INDs for drugs that entered clinical testing, and by 1981, four drugs had commercial sponsorship by the NDA stage (14, 15).

Although most of the federal funding for drug programs by the National Institutes of Health (NIH) was for the development of drugs for rare diseases—cancers and epilepsy—the NIH also devoted funding to development of other categories of orphan drugs. These included drugs to prevent and treat substance addiction and relapse, contraceptives for women of childbearing age, and some vaccines being developed by NIH and by the Centers for Disease Control (now the Centers for Disease Control and Prevention). Before 1983, when the Orphan Drug Act was signed into law, NIH drug development programs and grant-supported research had resulted in 13 drugs for the treatment of rare diseases being approved and on the market. In the 17 years before the Orphan Drug Law, the pharmaceutical industry had developed and marketed 34 drugs or biologicals for use in rare diseases or conditions (16). Ten of these marketed orphan drugs and biologicals had been developed solely by industry without government or university support (17).

The Gathering Storm

Nonetheless, several articles published in medical journals by academic researchers chronicled their plight in formulating new dosages for available drugs or

encapsulating chemical ingredients for clinical tests in patients with rare diseases, because no pharmaceutical sponsor had come to their rescue (18–20). One of these researchers, Cambridge University's John Walshe, proclaimed that this "do-it-yourself" problem had gone far enough and should be placed on a sound commercial basis (21). The FDA published a list of potentially promising therapeutic agents that were under development primarily by academic or government-based scientists who had failed to find commercial sponsors to undertake the costly phase III clinical trials for efficacy, file the NDA, and market the product (22). In 1979, the FDA convened a Task Force on Drugs of Little Commercial Value to determine how to find commercial sponsors. That same year, Louis Lasagna, who was then at the University of Rochester, invoked Provost's notion in an article in the journal *Regulation* by asking who will adopt the orphan drugs (23)?

NIH-funded academic researchers were reporting failed attempts to interest industry in taking on and securing NDA approval for drugs it had not developed. Industry had cited three major problems. First, NIH-funded scientists may not have gathered and analyzed data according to FDA requirements. Second, the trade secret status of data could not be preserved if the researcher had previously published information in the scientific literature. And third, many of the NIH-funded studies were of drugs that were not (or no longer) patentable. The FDA task force recommended that incentives be provided to industry to develop drugs of limited commercial value, but that any profits made from those incentives be returned, in whole or in part, to the government. (24). This arbitration-type approach was based on the assumption that industry would be willing to make trade-offs with the FDA on behalf of these drugs. But this assumption was made in the absence of any indication from industry that this was the case (25).

Although the task force was the first official policy response to the orphan drug situation (apart from the NIH-sponsored research responses), there were several private-sector efforts underway to promote the development and availability of orphan products. The Pharmaceutical Manufacturers Association (PMA, now called the Pharmaceutical Research and Manufacturers of America, or PhRMA) had been seeking sponsors among its member companies for promising orphan therapeutics. And a consumer group, the National Organization for Rare Disorders (NORD), was growing in number (now representing more than 20 million patients and their families) and undertaking efforts to raise public awareness and to help link patients to researchers conducting clinical studies of their diseases or conditions.

Lightning Strikes

A researcher at the Mount Sinai School of Medicine New York, who was seeking a pharmaceutical company sponsor for the drug L-5HTP for myoclonus, appealed to his Congressperson, Elizabeth Holtzman (D-New York) for a legislative remedy to the plight of orphan drug research. She introduced a bill in 1980 to establish the Office of Drugs of Limited Commercial Value to assist the NIH in developing drugs for the treatment of rare diseases (26). Although no action was taken on the bill, the committee heard testimony from a young California man suffering from Tourette's syndrome, a genetically determined neurological condition causing its victims to twitch, tic, and have uncontrollable verbal (and often abusive) outbursts. When haloperidol proved unsuccessful in controlling his symptoms, the patient had tried desperately to obtain and try pimozide, a drug available for the condition in Canada and Europe, but not in the United States.

A Los Angeles newspaper carried an account of the testimony, which caught the eye of the producer of the television series *Quincy*. Before long, a *Quincy* episode was devoted to dramatizing the conundrum of patients trying to cope with Tourette's syndrome and of industry trying to contend with the commercial disincentives to develop drugs to treat these patients. The episode demonstrated that there were no villains and no remedies. In a compelling scene before a Congressional committee, *Quincy* delivered an impassioned appeal to Congress to find a remedy. Shortly thereafter, *Quincy* star Jack Klugman was asked by Congressman Henry Waxman (D-California) to appear at a hearing on an orphan drug bill that was similar to Holtzman's, introduced by her colleague Representative Ted Weiss (D-New York). Klugman testified at the hearing, using the identical appeal he had delivered on the show (27). A *Wall Street Journal* editorial, entitled "Leave of Reality," likened Klugman's appearance before the Waxman subcommittee as an orphan drug expert to having Leonard Nimoy (Mr. Spock on *Star Trek*) testify as an expert on the nation's space program (28). By the end of 1981, Congressman Waxman had introduced H.R. 5238, the Orphan Drug Act.

The orphan drug survey

To find out the current status of development of drugs for the treatment of rare diseases, the subcommittee surveyed the industry, the NIH, and the FDA on three groups of drugs:

1. Products listed by PMA (now PhRMA) member companies as drugs for the treatment of rare diseases

- that industry sponsors had marketed or had made available on a compassionate basis to specialists;
2. Drugs and biologicals listed by the FDA as under development, but needing a commercial sponsor for FDA approval and marketing; and
 3. Drugs under development by NIH scientists or grantees.

From this survey, the Subcommittee learned that industry had marketed 34 drugs for the treatment of rare diseases extending back to 1965 and had made an additional 24 drugs (under development) available to physicians on a compassionate basis for treating patients with rare diseases. Most (82%) of the marketed drugs were for conditions affecting fewer than 100,000 people in the United States; 10% were for 100,000 to 500,000 people, and the remaining 8% were for up to 1 million people. Industry respondents indicated that substantial federal funding had been provided for research and/or development (R&D) for all but 10 of these marketed drugs.

The picture of disincentives confirmed claims by industry spokespeople sponsors indicated that the ROI for 83% of the drugs was lower than the sponsors' average return for marketed drugs, whereas development costs were higher than average for 12% of these drugs. Other issues cited by industry were the lack of clarity of FDA clinical testing guidelines when small numbers of patients were available and involved. This further eroded the sponsors' ability to estimate the length of clinical testing, and therefore the length of remaining patent protection time, once the drug was approved. Survey data indicated that industry-sponsored marketed orphan drugs took an average of 5.75 years for clinical testing (from filing the IND to filing the NDA). Unpatented orphan products were increasingly unlikely to be submitted for NDA approval, suggesting the importance of having at least some period of market protection. Whereas nearly two-fifths (39%) of industry-sponsored drugs for the treatment of rare diseases had been marketed in the 1960s, even though they were not protected by patent, this fell to 29% by the 1970s. Liability claims had been filed against the manufacturers of one-fifth of the marketed orphan drugs. The promising finding was that one in four industry-sponsored marketed orphan drugs also had a common indication. This suggested that orphan drugs were a relatively good market gamble (29).

Orphan Drug Act's Passage Provides Market Incentives and Regulatory Assistance

Based primarily on Congressional testimony marshaled by NORD revealing that millions of people and their families

were profoundly affected by rare diseases and conditions, and on survey data revealing market and regulatory disincentives to therapeutic progress, Congress passed the Orphan Drug Act during a lame duck session in December 1992. Called "the golden egg of the lame duck Congress" by the head of the Generic Pharmaceutical Industry Association (GPIA), the bill was signed into law the first week of January 1983 (30). The act (Public Law 97-414) was supported initially by the GPIA, which had begun seeking sponsors for developed orphan products, and eventually by the PMA after certain provisions were deleted or modified. Provisions in the law, and in subsequent amendments in 1984, 1985, and 1988, addressed market and regulatory issues and provided incentives for pharmaceutical industry development of drugs for the treatment of rare diseases.

The law, as amended, defines a rare disease or condition as one that affects fewer than 200,000 persons in the United States. Alternatively, the disease or condition can affect more than 200,000 persons in the United States, if there is no reasonable expectation that the cost of developing and making a drug available for such disease or condition in the United States will be recovered from U.S. sales of the drug. Therefore, a drug can be designated by the FDA as an orphan by demonstrating applicability of the law's financial criteria, regardless of the total number of people affected in the United States. Major provisions are the availability of two market incentives and the reduction of regulatory barriers. The FDA Office of Orphan Products Development administers nearly all the law's provisions.

One incentive is seven years of market exclusivity granted by the FDA for a specific indication of a product. Exclusivity begins on the date the FDA approves the marketing application for the designated orphan drug and applies only to the indication for which the drug has been designated and approved. An application for designation as an orphan drug for a specific indication must be made before submission of the NDA (or biologic product license application, PLA) for market approval (31). Other sponsors can receive approval for a different drug to treat the same rare disease or can receive approval to market an identical drug for some other orphan or common indication. Market exclusivity, therefore, only precludes a second sponsor from obtaining approval to provide an identical drug for the identical orphan indication for which the first sponsor received exclusive market approval. Initially, market exclusivity pertained only to unpatented products. A 1985 amendment allowed exclusive approval for all orphan drugs, whether patented or not. This change was designed to provide incentives for sponsors of products for the treatment of rare diseases whose patents

would expire before or soon after approval, or in cases in which prior publication (usually by an academic or government scientist) had precluded issuance of a patent.

A second incentive provides tax credits equal to 50% of the costs of human clinical testing undertaken in any given year by a sponsor to generate data required for obtaining FDA market approval through successful completion of the NDA process. The Internal Revenue Service administers the tax credit provisions.

The act provides for the FDA to award grants to support clinical studies of designated orphan products underdevelopment. FDA grant funding as of March 2000 from the FDA totaled \$126.3 million. From initial funding in 1983 of \$500,000 in grants, the grant program peaked in 1994 at \$12.3 million and has declined slightly but steadily thereafter, totaling \$11.1 million in 1999 (32). Applications are reviewed by outside experts and are funded according to a priority score. The FDA Office of Orphan Product Development provides information at its website (www.fda.gov/orphan/GRANTS/patients) on investigators seeking research subjects. Listed by the name of the disease or condition, information includes a description of the study, criteria for inclusion in clinical trials (such as age, stage of disease, etc.), and contact information on the clinical investigator seeking participants for clinical trials. Patients, their families, or their physicians are able to follow up with the clinical investigator.

To address regulatory barriers the FDA also provides formal protocol assistance when requested by the sponsor of an orphan drug. Although formal review of a request for protocol assistance is the direct responsibility of the FDA Centers for Evaluation and Research (one for drugs, the other for biologicals), the Office of Orphan Products Development is responsible for ensuring that the request qualifies for consideration. A sponsor need not have obtained orphan drug designation to receive protocol assistance.

Finally, the FDA is required to encourage sponsors to design open protocols for drug availability to patients not included in clinical trials.

The Current Status of Orphan Drugs

The FDA approved 201 orphan products between 1983 and March 2000 (33). In the 17 years since passage of the act, therefore, the number of approved orphan drugs has increased sixfold from the number approved in the 17 years before the act (Table 1). The drugs are classified within 16 therapeutic categories, primarily for the treatment of cancer, infectious disease, AIDS and related conditions, and central nervous system conditions (Table 2). Included in the 201 approved drugs are 24 (12%) that received FDA grant support for clinical trials (34). A list of these grant-supported products is available at the FDA Office of Orphan Products Development website (www.fda.gov/orphan/GRANTS).

The number of sponsors of approved orphan drugs (nearly all of them produced at pharmaceutical or biotechnology companies) has increased from 17 (for the 34 drugs marketed before the act) to 110 as of March 2000. The number of approved drugs per sponsor ranges from one to eight, with a preponderance of one-drug sponsors (Table 3). A total of 813 products have received orphan designations as of March 2000. Sponsors of approximately 25% of these designated products have filed INDs for the products, indicating that they are under active development (35).

Many of the designated and approved orphan products are developed at biotechnology companies. Beginning in the 1970s, molecular biology had begun to spur the creation of biotechnology research companies. These companies reportedly recognized early on that market exclusivity, and lack of competition to develop products for the treatment of rare diseases, provided protection essential to raising venture capital. As a result, orphan drugs are now among biotechnology's most prevalent, and, according to some, most lucrative products. Between 1988 and 1992, biotechnology product designations increased by 31%, from 8 to 39% of total orphan designations (36). In addition to industry, however, sponsors have included a university, an individual researcher, and a state public health unit, which in aggregate sponsored six orphan drugs at the time of approval. Lists of approved and designated orphan drugs can be obtained from the FDA Office of Orphan Products Development. These data suggest that orphan drug development has consistently risen over the years since the law was enacted. Aggregate sales of

orphan drugs have been reported to be more than \$1 billion a year (37).

A Resulting Issue: High Pricing for Some Products

By the early 1990s, U.S. sales data collected for 41 of the approved orphan drugs that had been on the market for a year or more indicated that 75% of the products had generated earnings of less than \$10 million per drug. Three products had earnings between \$10 and \$25 million, six

drugs between \$26 and \$100 million, and two products more than \$100 million. Biotechnology firms produced four of the 11 drugs with relatively high sales.

Those orphan drugs that command high prices have generated intense controversy over whether the market exclusivity provision is creating an unnecessary monopoly, keeping prices artificially high. One example is recombinant human erythropoietin (r-EPO), intended for patients with chronic renal failure-related anemia. EPO eliminates the need for frequent blood transfusions by patients with end-stage renal disease who are undergoing kidney dialysis. These patients are covered under the federally financed Medicare program. Both Amgen Inc. and Genetics Institute applied to the FDA for market exclusivity for their r-EPO products. Amgen was the first to receive FDA approval and market exclusivity. Genetics Institute was the first to receive a patent. On appeal, the court ruled that Amgen had exclusive marketing rights. Sales of r-EPO exceeded \$100 million in the first six months of marketing, paid for by Medicare. By 1991, sales totaled \$400 million (38).

Human growth hormone (r-hGH), another example, generated sales of \$150 million in 1991. Intended to treat approximately 12,000 children in the United States with retarded growth caused by a lack of endogenous pituitary hormone, two companies provide r-hGH. Genentech received FDA market exclusivity in 1985. Eli Lilly received market approval two years later, based on the determination that the two products differed by one amino acid (39,40). But the shared market did not lead to price competition: each company was earning approximately \$20,000 per child annually, depending on the dosage needed.

A third example, aerosol pentamidine, generated sales of \$130 million in 1991. Helping to prevent *Pneumocystis carinii* pneumonia associated with the human immunodeficiency virus (HIV), the increasing number of users resulting from a rapidly escalating HIV prevalence rate was expected to soon exceed the 200,000 population figure specified in the law. This example, along with the other two, prompted efforts to seek a legislative remedy. A series of amendments were introduced and passed by Congress in 1990 that sought to eliminate orphan status for products intended for use in epidemics and to allow shared market access for identical products developed simultaneously for the same indication, in the hope that this would lead to price competition. The amendments were vetoed (41). As Arno, Bonuck, and Davis present in *Milbank Quarterly*, AIDS treatment drugs exemplify the policy dilemma of how to use the Act to meet the legislative intent of stimulating development of drugs for small patient populations without resulting in prices that make such drugs inaccessible (42).

^aDoes not include sponsors of drugs for rare diseases approved before the Orphan Drug Act of 1983.

Another, more recent, example is enzyme therapy for Gaucher's disease, an inborn error of metabolism, treated with Ceredase. The therapy, which requires more than a ton of placenta annually to extract and make the drug, can cost as much as \$500,000 per year per person, depending on the dosage needed. A 1996 National Institutes of Health technology assessment panel addressed issues in diagnosis and treatment of the disease and concluded that despite the success of enzyme therapy, treatment is limited by the cost. The panel reported that it was imperative to define the appropriate clinical indications for treatment and to determine the lowest effective initial and maintenance doses (43).

Although the survey undertaken prior to the Act found that retail costs of drugs for the treatment of rare diseases were reportedly higher than the manufacturer's average for 60% of the products marketed before the act, the pricing for some orphan drugs after the act, as exemplified by these examples, is a critically important consequence of the law. This consequence merits continued public scrutiny. It is a sign of progress that for some orphan drugs, accessibility rather than availability is now the challenge requiring creative solutions.

NANOPARTICLES AS DRUG DELIVERY SYSTEMS

Elias Fattal

Christine Vauthier

University of Paris XI, Châtenay-Malabry, France

INTRODUCTION

Nanoparticles are small colloidal particles which are made of non biodegradable and biodegradable polymers. Their diameter is generally around 200 nm. One can distinguish two types of nanoparticles (Fig. 1): nanospheres, which are matrix systems; and nanocapsules, which are reservoir systems composed of a polymer membrane surrounding an oily or aqueous core. These systems were developed in the early 1970s. This approach was attractive because the methods of preparation of particles were simple and easy to scale-up. The particles formed were stable and easily freeze-dried. Due to these reasons, nanoparticles made of biodegradable polymers were developed for drug delivery. Indeed, nanoparticles were able to achieve with success tissue targeting of many drugs (antibiotics, cytostatics, peptides and proteins, nucleic acids, etc.). In addition, nanoparticles were able to protect drugs against chemical and enzymatic degradation and were also able to reduce side effects of some active drugs. This review focuses on the preparation and characterization methods of nanoparticles. The main applications of these systems are also described.

PREPARATION OF NANOPARTICLES

Polymer nanoparticles including nanospheres and nanocapsules (Fig. 1) can be prepared according to numerous methods that have been developed over the last 30 years. The development of these methods occurred in several steps. Historically, the first nanoparticles proposed as carriers for therapeutic applications were made of gelatin and cross-linked albumin (1, 2). Then, to avoid the use of proteins that may stimulate the immune system and to limit the toxicity of the cross-linking agents, nanoparticles made from synthetic polymers were developed. At first, the nanoparticles were made by emulsion polymerization of acrylamide and by dispersion polymerization of methyl-methacrylate (3, 4). These nanoparticles were proposed as adjuvants for vaccines. However, since they were made of nonbiodegradable polymers, these nanoparticles were

rapidly substituted by particles made of biodegradable synthetic polymers. Couvreur et al. (5) proposed to make nanoparticles by polymerization of monomers from the family of alkylcyanoacrylates already used in vivo as surgical glue. They succeeded in making nanoparticles by polymerization of the monomers in oil-in-water type emulsions prepared with an acidified aqueous phase. During the same period of time, Gurny et al. (6) proposed a method based on the use of another biodegradable polymer consisting of poly(lactic acid) used as surgical sutures in humans. In this method, nanoparticles were formed directly from the polymer. Based on these initial investigations, several groups improved and modified the original processes mainly by reducing the amount of surfactant and organic solvents. At that time, the methods developed were only able to produce nanospheres (Fig. 1A). A breakthrough in the development of nanoparticles occurred in 1986 with the development of methods allowing the preparation of nanocapsules corresponding to particles displaying a core-shell structure with a liquid core surrounded by a polymer shell (7–9) (Fig. 1B). From 1986, there was also an acceleration in the development of new methodologies for the preparation of all types of nanoparticles. The nanoprecipitation technique was proposed (10) as well as the first method of interfacial polymerization in inverse microemulsion (11). In the following years, the methods based on salting-out (12), emulsion–diffusion (13, 14), and double emulsion (15) were described. Finally, during the last decade, new approaches were considered to develop nanoparticles made from polysaccharides based on the gelation properties of these natural macromolecules (16). These nanoparticles were developed for peptides and nucleic acid delivery. Another goal was the development of surface modified nanoparticles to produce long circulating particles able to avoid the capture by the macrophages of the mononuclear phagocyte system after intravenous administration (17).

All the methods can be classified into two groups depending on whether the nanoparticles are formed at the same time than the polymer itself requiring a polymerization reaction or are directly obtained from a polymer. There are numerous valuable reviews on the subject (9, 18–21). The general principles of the methods leading

Fig. 1 Schematic representation of a nanosphere (A) and of a nanocapsule (B). In nanospheres, the whole particle consists of a continuous polymer network. Nanocapsules present a core-shell structure with a liquid core surrounded by a polymer shell.

to nanoparticle preparation are described and details of the most representative over are given.

Preparation of Nanoparticles by Polymerization

Nanospheres are mostly prepared by emulsion polymerization whereas nanocapsules are obtained by interfacial polymerization performed in emulsion or in microemulsion. In emulsion polymerization, the monomer itself, if liquid, is dispersed under agitation in a continuous phase in which it is nonmiscible. The polymerization is usually initiated by the reaction of the initiators with the monomer molecules that are dissolved in the continuous phase of the emulsion. The polymerization continues by further addition of monomer molecules that diffuse toward the growing polymer chain through the continuous phase. The growing polymer chain remains soluble until it reaches a certain molecular weight for which it becomes insoluble.

Therefore, phase separation occurs leading to the nucleation of the polymer particles and the formation of the tyndall scattering effect. Further growth of the nucleated particles occurs according to a mechanism that depends on the stability conditions of the whole system. This includes capture of new growing polymer chains, fusion or collision between nucleated particles (22). Throughout the polymerization, the monomer input in the continuous phase of the emulsion takes place by diffusion from the monomer droplets, which play the role of monomer reservoirs. When the reaction is completed, the particles formed contains a large number of polymer chains (19, 22). Emulsion polymerization can be performed in emulsifier free systems and in both oil-in-water and water-in-oil emulsions.

The poly(alkylcyanoacrylate) nanospheres, widely used as drug carriers, are prepared by emulsion polymerization according to a method initially introduced by Couvreur et al. (5). The monomers (isobutylcyanoacrylate, isohexylcyanoacrylate, *n*-butylcyanoacrylate) are dispersed in a continuous acidified aqueous phase under magnetic agitation. The anionic polymerization of the alkylcyanoacrylate is rapidly and spontaneously initiated by the remaining OH^- ions of the acidified water and is completed within 3–4 h depending on the monomer type (Fig. 2). The preparation is performed at low pH (pH ~ 2.5) to slow down the anionic polymerization of the alkylcyanoacrylate, therefore allowing the polymer to arrange as colloidal particles. Dextran 70 or Pluronic[®] F68 are usually dissolved in the aqueous phase to ensure the stability of the polymer particles. The size of the nanospheres can be controlled by the amount of Pluronic[®] F68 from a diameter of 40–250 nm for

Fig. 2 Anionic polymerization of alkylcyanoacrylate initiated by the OH^- from the dissociation of the water molecule.

concentrations ranging from 3 to 0%, respectively (23). Numerous drugs have been associated with these nanospheres including doxorubicin, an anticancer agent, a peptide growth hormone, and several antibiotics. Antisense oligonucleotides were adsorbed on the nanosphere surface via the formation of an ion-pair with a cationic surfactant, cetyltrimethylammonium bromide. Finally, it should be mentioned that some drugs can lose their biological activity during the preparation of poly(alkylcyanoacrylate) nanospheres. Generally, these molecules contain chemical functions that are able to initiate the polymerization of alkylcyanoacrylates and be covalently attached to the polymer constituting the nanospheres. The mode of such an interaction has been elucidated for two molecules including phenylbutazone (an anti-inflammatory drug) and vidarabine (an antiviral molecule). In contrast, the side reactions can be used to achieve the covalent linkage of defined compounds to give specific properties to the nanospheres. This has been used with poly(ethylene glycol) that initiated the polymerization of isobutylcyanoacrylate to give poly(ethylene glycol)-coated nanospheres, therefore presenting a more hydrophilic surface than those prepared according to the original method (24).

Methylidene malonates are other monomers that give biodegradable polymers and polymerize according to a similar mechanism than alkylcyanoacrylates. These monomers were also used to make nanospheres by emulsion polymerization for drug delivery (25).

Nanocapsules can be prepared by interfacial polymerization of alkylcyanoacrylates (7). The main advantage of using these monomers is their very fast polymerization rate when they come into contact with water. Oil containing nanocapsules were prepared by the rapid dispersion of an ethanol phase including ethanol, the oil, the monomer, and the molecule to be encapsulated in an aqueous solution of surfactant. When the ethanol diffuses in the aqueous phase, tiny individual oil droplets form, and because of the contact with water at the oil/water interface, the polymerization of the alkylcyanoacrylate takes place on the droplet surface (26). This method is mainly adapted for the encapsulation of oily soluble substances (9). However, surprisingly, highly water-soluble molecules such as insulin could be entrapped in these nanocapsules with high encapsulation yields (up to 97%) (27).

Water containing nanocapsules were prepared by interfacial polymerization of the alkylcyanoacrylate in water-in-oil microemulsions. In these systems, water swollen micelles of surfactants of small and uniform sizes are dispersed in an organic phase. To prepare nanocapsules, the monomer is added to the oily phase of the

already prepared microemulsion. The anionic polymerization of the alkylcyanoacrylate is initiated at the surface of the water swollen micelles and the polymer formed locally to make the shells of the nanocapsules. In the method first introduced by Gasco and Trotta (11), the microemulsions were prepared with hexane as the organic phase and Aerosol-OT as the surfactant. Both of these constituents are not compatible for the development of an acceptable drug carrier system. Thus, the method was recently adapted to microemulsions formulated with more biocompatible compounds, but still quite high concentrations of surfactant (up to 14 wt%) are required for their preparation (28). The nanocapsules obtained by this method are dispersed in an organic medium and can mainly be used for oral administration. Indeed, for intravenous administrations, it is necessary to transfer the nanocapsules into an aqueous continuous phase. Such a transfer still remained a problem until recently, since the total elimination of the organic phase and the redispersion of the nanocapsules, in water is a difficult task to achieve avoiding the aggregation of the nanocapsules. Recently, Lambert et al. (29) proposed to perform this operation by ultracentrifugation of the nanocapsule dispersion over a layer of pure water. Using this simple approach, the nanocapsules transferred from the organic phase to the aqueous phase without any aggregation problem during the centrifugation. In addition, this technique allows the elimination of the excess surfactant, which remains in the organic phase. This nanoencapsulation method has special interest for the encapsulation of water soluble molecules such as peptides (28) and nucleic acids including antisense oligonucleotides (29).

Preparation of Nanoparticles Using a Polymer

In this group of methods, the nanoparticles are obtained from a polymer, which was prepared according to a totally independent method. This approach presents the major advantage that the polymers entering the composition of the nanoparticles are well characterized and their intrinsic physicochemical characteristics will not depend on the conditions encountered during the preparation of the nanoparticles as it can be the case with the previously described methods. Most methods starting from polymers have taken advantages of the physicochemical properties of the polymer used in terms of its solubility or its faculty to form a gel under certain conditions. Basically, two approaches are followed. One is based on the spontaneous formation of colloidal particles of the polymer that are then stabilized in a second step of the procedure. The second approach is based on the adaptation of methods initially developed to make microparticles. In this case, the

goal is to reduce the size of the particles formed with these methods. A third approach leading to the formation of very specific particles named SupraMolecular BioVectors by their authors (30) is described separately. The different ways to produce nanoparticles from a polymer is summarized in Fig. 3.

Methods based on the spontaneous formation of the nanoparticles

Spontaneous formation of nanoparticles can be achieved by taking advantage of the solubility and gelling properties of a dissolved polymer. Usually, the step allowing polymer colloidal particles to form is reversible, and it is necessary to complete the procedure by a second step required to stabilize the particles.

Based on the solubility properties of a polymer, the general principle is to prepare a solution of the polymer and to induce a phase separation by the addition of a nonsolvent of the polymer (10) or by a salting-out effect (2). The occurrence of the phase separation can be followed by turbidimetric measurements (2) or investigated using ternary phase diagrams (31). Phase separations leading to polymer colloid particles are usually obtained with diluted solutions of polymers. In a ternary phase

diagram, it corresponds to a small domain. Using higher polymer concentrations in the solvent, the colloidal particles formed at the limit of the phase separation as followed by turbidimetric measurements in the case of proteins. To facilitate the formation of colloidal dispersion of polymer particles, it is better to induce the phase separation in totally miscible solvent–nonsolvent systems. At that stage, the particles form spontaneously and quasi-instantaneously.

Once the proper conditions to obtain the polymer colloidal nanoparticles are identified, the particles must be stabilized. This is usually achieved either by the elimination of the polymer solvent by evaporation or by chemical cross-linking of the polymer as it is the case with proteins (32).

This method, also known as the nanoprecipitation method, can be applied to numerous synthetic polymers (10, 31). In general, the polymer is dissolved in acetone and the polymer solution is added into water. The acetone is then evaporated to complete the formation of the particles. Surface active agents are usually added to water to ensure the stability of the polymer particles. This easy technique of nanoparticle preparation was scaled up for large batch production. It leads to the formation of

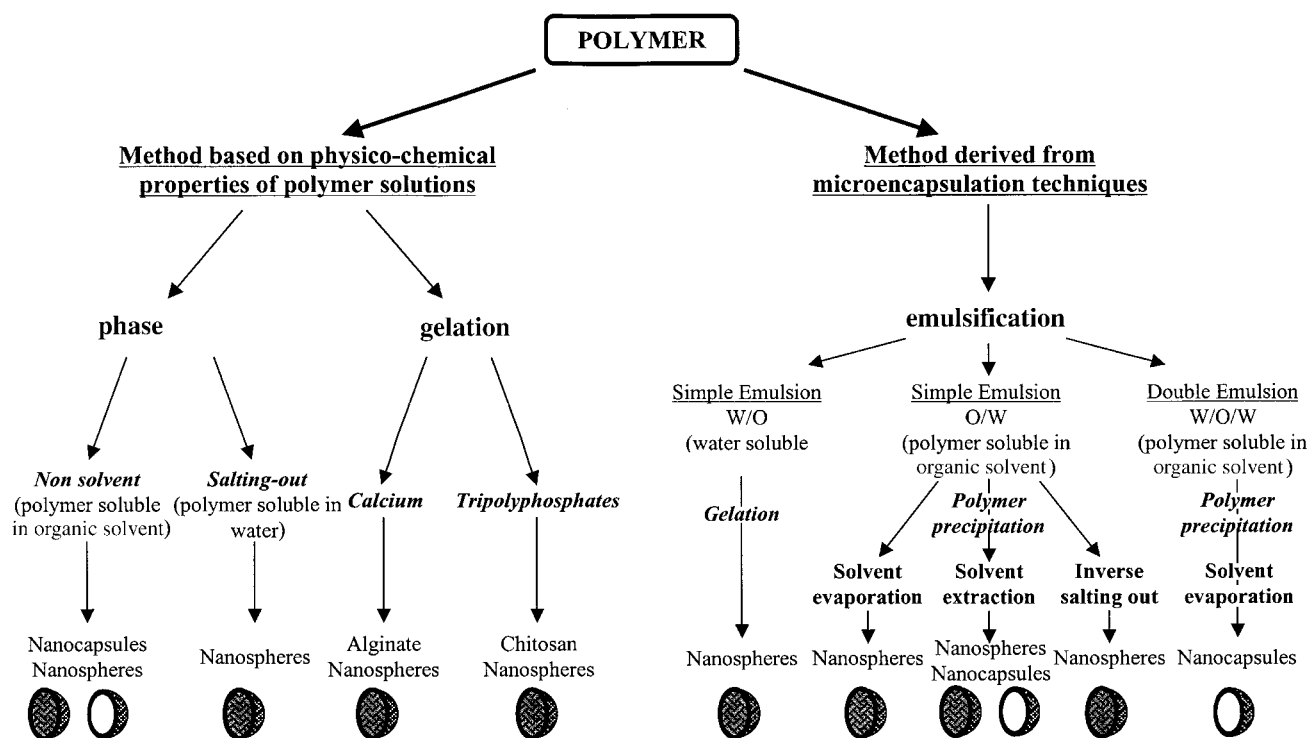

Fig. 3 Summary of the different methods to prepare nanospheres and nanocapsules from a polymer. W/O: water-in-oil, O/W: oil-in-water, W/O/W: water-in-oil-in-water.

nanospheres. Nanocapsules can easily be prepared by the same method just by adding a small amount of an organic oil in the polymer solution (8, 9). When the polymer solution is poured into the water phase, the oil is dispersed as tiny droplets in the solvent–nonsolvent mixture and the polymer precipitates on the oil droplet surface. This method leads to the preparation of oil-containing nanocapsules and can be valuably used for the encapsulation of liposoluble drugs.

Techniques based on the use of proteins are much more adapted to the encapsulation of hydrosoluble compounds and were recently developed to produce gelatin nanospheres as carrier systems for gene delivery (33, 34).

Based on the gelation properties displayed by certain polymers, nanoparticles are formed spontaneously by controlling the gelation process. This approach has been developed with alginate and chitosan that form highly water-swollen gels. The gelling agents for these two natural polysaccharides are respectively calcium and tripolyphosphate. Nanoparticles are formed in a certain domain of concentrations of the polysaccharide and of the gelling agent (35, 36). With the alginate, it has been shown that nanoparticles can be prepared when the respective concentrations of alginate and calcium are comprised in the domain of the pregel stage of the alginate gelling process (alginate 0.6 wt%, calcium chloride 0.9 mM). At this composition, tiny particles of gels form resulting from inter and intramolecular aggregations of alginate molecules caused by the interaction with calcium. These aggregates are stabilized by the formation of a polyelectrolyte complex with polylysine. Alginate and chitosan nanoparticles are interested for nucleic acid and protein delivery as recently reviewed by Vauthier and Couvreur (16).

Methods derived from microencapsulation techniques

Methods derived from microencapsulation techniques require the formation of an emulsion as a first step of the procedure. To produce nanometer-scale-sized particles, the size of the emulsion droplets must be small enough. This can be achieved by the use of special equipments such as high pressure homogenizers and microfluidizers. The energy input produced by these apparatus is important and is mainly due to high turbulence and cavitation forces. It allows an efficient dispersion of the polymer solution in the continuous phase. Once the desired emulsion is prepared, the formation of the nanoparticles can be induced according to two routes including the gelation of the polymer and the precipitation of the polymer either by solvent displacement or by solvent evaporation. Gelation can be induced by increasing the pH, adding calcium, or decreasing the temperature of emulsions containing

respectively, chitosan, alginate, and agarose (16). In the solvent displacement technique, the emulsion is formed with a solvent of the polymer, which is partially soluble in water and with an aqueous phase saturated with the solvent. Once the emulsion is formed with ethylacetate as an example, it is diluted by the further addition of water to displace the solvent from the dispersed phase inducing the polymer precipitation (14). This principle was also developed on the base of an inverse salting-out method (12). In this procedure, a solution of polymer in acetone is dispersed in an aqueous phase containing a high concentration of salt to keep the acetone nonmiscible with water. Just by diluting the emulsion with a large amount of pure water, the acetone is then extracted from the dispersed phase inducing the polymer precipitation. The total elimination of the acetone can be achieved by evaporation. Finally, precipitation of the polymer solubilized in the dispersed phase can also be induced by the removal of the solvent by evaporation (6, 37). In this method named emulsification-solvent evaporation, the polymer solvent diffuses through the aqueous continuous phase and evaporates at the air/water interface. The emulsion should remain under agitation during the time required for the total evaporation of the solvent. These methods produce nanospheres. To make nanocapsules, small amounts of oil can be added in the dispersed phase of the emulsion that will form the nanocapsules by solvent displacement (13). Nanocapsules can also be prepared with the solvent evaporation technique from a double water-in-oil-in-water emulsion (15). The removal of the organic solvent of the intermediate phase of this double emulsion by evaporation causes the polymer to precipitate at the surface of the inner aqueous phase. Whereas nanocapsules made by the solvent displacement method is more adapted for the encapsulation of lipophilic compounds, this last method allows the encapsulation of hydrosoluble compounds.

Preparation of SupraMolecular BioVector

SupraMolecular BioVector consists of polysaccharide nanospheres surrounded by a bilayer of phospholipids (30). At the origin, these systems were developed to mimic the low density lipoproteins that are natural colloidal structures encountered in the blood circulation and designed for the transport of cholesterol and cholesterol esters *in vivo*. SupraMolecular BioVector are prepared in several steps including the fonctionnalization and chemical cross-linking of a polysaccharide (starch or dextran), the purification and the drying of the modified polysaccharide followed by the fragmentation of the resulted powder under high pressure to produce small

polysaccharide nanoparticles. Finally, a lipid bilayer is adsorbed on the surface of the nanoparticles. The chemical modification of the polysaccharide forming the core of the SupraMolecular BioVector lead to various possibilities in terms of the type of molecules that can be associated with such a carrier system. Indeed, the polysaccharide core can be either negatively or positively charged or even neutral opening large application potential.

Preparation of Surface Modified Nanoparticles

Once intravenously administered, the body distribution of the nanoparticles is controlled by their surface properties. Indeed, despite their small size, nanoparticles display an enormous specific surface area that makes the interaction with the surrounding medium very important especially for their fate *in vivo*. Thus, the preparation of surface modified nanoparticles received much attention during the last decade to produce nanoparticles that are able to circulate for a long period of time in the blood stream at first and, more recently, to achieve an effective targeting of the device or to improve their bioadhesivity to mucosae.

Nanoparticles that are able to circulate for a long time in the blood stream should not be recognized by macrophages of the mononuclear phagocyte system. To achieve this goal, at least one of the two major known mechanisms involved in the recognition of foreign particles by macrophages should be avoided. These two mechanisms include the particle opsonization and the complement activation, which consists in protein adsorption and subsequent recognition by macrophages. A barrier to protein adsorption could be achieved by creating an efficient barrier of steric hindrance, therefore, by coating or adsorbing hydrophilic polymers to nanoparticle surface.

Nanospheres coated with poly(ethylene glycol) were first obtained by the simple adsorption of triblock copolymers of poly(ethylene glycol)–poly(propylene glycol)–poly(ethylene glycol) on the surface of already prepared nanospheres (38). To improve the stability of the poly(ethylene glycol) coating, nanospheres were prepared by nanoprecipitation or by emulsification-solvent evaporation using copolymers of poly(lactic acid)–co-poly(ethylene glycol) or of poly(alkylcyanoacrylate)–co-poly(ethylene glycol) (17, 39–41). Finally, poly(ethylene glycol) can initiate the polymerization of alkylcyanoacrylate to produce poly(ethylene glycol)-coated poly-(alkylcyanoacrylate) nanoparticles by emulsion polymerization (24, 41).

To make nanoparticles able to escape complement activation, Passirani et al. (42) proposed to coat

nanospheres with heparin. This compound, which is a polysaccharide, is a physiological inhibitor of complement activation *in vivo*. Heparin-coated poly(methylmethacrylate) nanoparticles were prepared by emulsion polymerization. In the method, the radical polymerization of methylmethacrylate was initiated by heparin according to an original method involving cerium ions and allowing heparin to covalently attach to poly(methylmethacrylate).

The next step now is the development of targeted nanoparticles toward a specific cell type. This has recently been investigated by Stella et al. (43) who prepared poly(alkylcyanoacrylate) nanoparticles showing residues of folic acid on their surface. These nanoparticles will be used to target cancer cells overexpressing a membrane receptor for the folic acid. The targeting moiety, consisting on the folic acid, was grafted on the surface of poly(aminopoly(ethylene glycol) cyano-co-hexadecylcyanoacrylate) nanoparticles that were obtained by nanoprecipitation.

In another way, chitosan was used as a coating agent for nanoparticles to improve their bioadhesive properties after oral and nasal administration (44). Indeed, chitosan is known to have bioadhesive properties as well as an interesting absorption enhancing capacity.

CHARACTERIZATION OF NANOPARTICULATE DRUG CARRIERS

Nanoparticles can be characterized by all the different physico chemical techniques that apply for polymer colloids (45). Concerning the development procedure of nanoparticles as drug carriers, the main physico chemical parameters that are investigated are the shape, the size, the surface properties, the density, and the concentration of the particles (19). The size as well as the size distribution are important parameters to be determined to achieve safe intravenous administration. Surface properties are also important to consider as nanoparticles display considerable specific surface area responsible for the interactions with the surrounding medium. Finally, the density and the concentration are required to deduce the specific surface area of the particles together with the size.

Nanoparticles can be visualized using different microscopy techniques. Transmission electron microscopy is usually applied to nanoparticles after negative staining with phosphotungstate acid or with uranyl acetate after it has been checked that the staining agents do not modify the particles. Recent progress in transmission electron microscopy now allows direct observations of the nanoparticles without the use of any staining agent that

may cause artefacts in some cases. In particular, direct observations of the nanoparticles after a sample of the nanoparticle dispersion has been freezing at very low temperature can be carried out by cryotransmission electron microscopy. Scanning electron microscopy is performed on samples coated with a thin layer of gold metal to produce the contrast. These techniques as well as those based on atomic force microscopy give useful images of the nanoparticles showing their shape. Measurements of the size and of the size distribution require determination of the diameters number of individual nanoparticles that may be assisted by the use of valuable image analysis softwares. The internal structure of the nanoparticles can be observed by freeze fracture and cryotransmission electron microscopy.

Generally, mean size and size distribution of nanoparticles are evaluated by quasi-elastic light scattering also named photocorrelation spectroscopy. This method is based on the evaluation of the translation diffusion coefficient, D , characterizing the Brownian motion of the nanoparticles. The nanoparticle hydrodynamic diameter, d_H is then deduced from this parameter from the Stokes Einstein law.

Other techniques can be used to determine the size and the size distribution of the nanoparticles. The field flow fractionation method is based on the separation of particles according to their size in a thin glass channel in which the flow carrying on the nanoparticles is submitted to an external perpendicular force produced either by a crossed flow or a sedimentation (46, 47). This technique, which can be applied for particles in a wide range of size (10 nm to several hundred μm), will gain more attention in the future for size determination and also for nanoparticle surface analysis (48). Size and size distribution of nanoparticles can also be determined by size exclusion chromatography performed on appropriate gels. This approach, requiring less equipment than the previous methods, presents the main limitation that only particles having a diameter lower than 120 nm can be characterized by this method (49).

As mentioned earlier, surface characteristics of the nanoparticles are of primary importance for the interaction of the nanoparticles with the surrounding medium. The main nanoparticle surface characteristics that are considered are the charge, the hydrophilicity, the chemical composition and the capacity to adsorb proteins and to induce complement activation.

The charge of the nanoparticle surface is usually evaluated by the measurement of their zeta potential, which gives information about the overall surface charge of the particles and how it is affected by changes in the environment (50). Zeta potential is affected by the surface

composition of the nanoparticles, the presence or the absence of adsorbed compounds, and the composition of the dispersing phase, mainly the ionic strength and the pH.

The hydrophilicity of the nanoparticle surface can be evaluated by hydrophobic interaction chromatography (51). This technique, based on affinity chromatography, allows a very rapid discrimination between hydrophilic and hydrophobic nanoparticles. The nanoparticles are passed through a column containing a hydrophobic interaction chromatography gel. The nanoparticles that are retained by the gel and only eluted after the addition of a surfactant are considered as hydrophobic, whereas the nanoparticles that do not interact with the gel and that are directly eluted from the column are considered as hydrophilic. Apart from the hydrophobic interaction chromatography, the field flow fractionation techniques recently appeared to present interesting potential for the characterization of nanoparticles with different surface characteristics (48).

X-ray photoelectron spectroscopy (ESCA) can be used to determine the chemical composition of the nanoparticle surface. This technique is a very useful tool for the development of surface modified nanoparticles providing a direct evidence of the presence of the components that are believed to be on the nanoparticle surface (38, 41).

The capacity of the nanoparticles to adsorb proteins and to activate the complement *in vivo* after intravenous administration will influence the fate of the carrier and its body distribution. To approach this aspect, *in vitro* tests have been developed to investigate the profile of the type of serum proteins that adsorbed onto the nanoparticle surface after incubation in serum and to evaluate the capacity of the nanoparticles to induce complement activation. The analysis of the protein adsorbed onto the nanoparticle surface can be performed by 2D-polyacrylamide gel electrophoresis. This technique allows the identification of the proteins that adsorbed onto the nanoparticle surface (52). To evaluate modifications of the composition of the adsorbed protein with time, a faster method based on capillary electrophoresis can also be used (53). Finally, the activation of the complement produced by nanoparticles can be evaluated either by a global technique or by a specific method measuring the specific activation of the component C3. In the global technique, nanoparticles are incubated with serum and, after the incubation, the remaining nonactivated complement in the serum is evaluated using a red blood cell lysis test (54, 55).

The concentration of nanoparticle in the dispersion can be deduced from gravimetric determination or by turbidimetric measurements based on the application of the Mie's law (48, 56). Density of the nanoparticles is evaluated

either by pycnometry (57) or by isopycnic centrifugation (13, 58).

PHARMACEUTICAL APPLICATIONS OF NANOPARTICLES

Nanoparticles were first developed in the mid-seventies by Birrenbach and Speiser (3). Later on, their application for the design of drug delivery systems was made available by the use of biodegradable polymers that were considered to be highly suitable for human applications (5). At that time, the research on colloidal carriers was mainly focusing on liposomes, but no one was able to produce stable lipid vesicles suitable for clinical applications. In some cases, nanoparticles have been shown to be more active than liposomes due to their better stability (59). This is the reason why in the last decades many drugs (e.g., antibiotics, antiviral and antiparasitic drugs, cytostatics, protein and peptides) were associated to nanoparticles.

Intravenous Administration

Fate of nanoparticles and their content after intravenous administration

The main interest of nanoparticles is their ability to achieve tissue targeting and enhance the intracellular penetration of drugs. After intravenous administration, nanoparticles are taken up by the liver, spleen and to a lower extent the bone marrow (60). Within these tissues, nanoparticles are mainly taken up by cells of the mononuclear phagocyte system (MPS) (61). The uptake occurs through an endocytosis process after which the particles end up in the lysosomal compartment (61) where they are degraded producing low molecular weight soluble compounds that are eliminated from the body by renal excretion (62). As a result of the MPS site specific targeting, avoidance of some organs was made possible, thus reducing the side effects and toxicity of some active compounds. Due to their strong lysosomal localization, one could imagine that nanoparticles are not suitable to target to the cytoplasm. To avoid their trapping within the lysosomal compartment, several compounds able to destabilize the lysosomal membrane were added to the nanoparticulate systems (e.g., cationic surfactant) (63) allowing some drugs to be delivered to the cytoplasm. Recently, to avoid MPS uptake, several groups have developed a strategy consisting of the linkage to the nanoparticles of poly(ethylene glycol) derivatives (39, 64, 65). This linkage results in a lower uptake of nanoparticles by the MPS and in a longer circulation

time. As a consequence, these so-called stealth[®] nanoparticles would be able to extravasate across endothelium that becomes permeable due to the presence of solid tumors.

Application to the treatment of intracellular infections

Intracellular infections were found to be a field of interest for drug delivery by means of nanospheres. Indeed, infected cells may constitute a "reservoir" for micro organisms, which are protected from antibiotics inside lysosomes. The resistance of intracellular infections to chemotherapy is often related to the low uptake of commonly used antibiotics or to their reduced activity at the acidic pH of lysosomes. To overcome these effects, the use of ampicillin, a β lactam antibiotic, bound to nanospheres was proposed as endocytosable formulation (66). The effectiveness of polyisohexylcyanoacrylate (PIHCA) nanospheres was tested in the treatment of two experimental intracellular infections.

Firstly, ampicillin-loaded nanospheres were tested in the treatment of experimental *Listeria monocytogenes* infection in congenitally athymic nude mice, a model involving a chronic infection of both liver and spleen macrophages (67). After adsorption of ampicillin onto nanospheres, the therapeutic activity of ampicillin was found to increase dramatically over that of the free drug. Bacterial counts in the liver were at least 20-fold reduced after linkage of ampicillin to PIHCA nanospheres. In addition, nanoparticulate ampicillin was capable of ensuring liver sterilization after two injections of 0.8 mg of nanospheres bound drug, whereas no such sterilization was ever observed with any of other regimens tested. Reappearance of living bacteria in the liver after the end of the treatment was probably due to a secondary infection derived from other organs such as the spleen, which was not completely sterilized by the treatment (67).

Secondly, nanosphere-bound ampicillin was tested in the treatment of experimental salmonellosis in C57/BL6 mice, a model involving an acute fatal infection (66). All mice treated with a single injection of nanoparticle-bound ampicillin survived, whereas all control mice and all those treated with unloaded nanospheres died within 10 days postinfection. With free ampicillin, an effective-curative effect required three doses of 32 mg each. Lower doses (3×0.8 mg and 3×16 mg) delayed but did not reduce mortality. Thus, the therapeutic index of ampicillin, calculated on the basis of mice mortality, was increased by 120-fold when the drug was bound to nanospheres.

In order to clarify the mechanism by which nanospheres improved the antimicrobial efficacy of ampicillin, Forestier et al. (68) have compared in vitro the efficacy of ampicillin bound to poly(isobutylcyanoacrylate) (PIBCA)

nanospheres with that of free ampicillin in terms of survival of *L. monocytogenes* in mouse peritoneal macrophages. After 30 h of incubation, nanosphere-bound ampicillin decreased the number of viable bacteria by 99% as compared to the controls whereas with free ampicillin, the number of bacteria was slightly lower than in the controls. Nanoparticle-ampicillin thus appeared to be much more effective than free ampicillin for inhibiting intracellular growth of *L. monocytogenes*. With in vitro *Salmonella typhimurium* infected macrophages, the situation was a little bit more complicated since the bactericidal effect of ampicillin-bound PIHCA nanospheres was poor although the intracellular capture of ampicillin was dramatically increased and its efflux in the extracellular medium reduced (69). In another study, confocal microscopy and transmission electron microscopy were used to establish the intracellular traffic of ampicillin-bound PIHCA nanospheres and its relation with the bacteria within the subcellular compartments (70). The data obtained clearly demonstrated the active uptake by phagocytosis of ampicillin-bound PIHCA nanospheres by murine macrophages and their localization in the same vacuoles as the infecting bacteria, but in a restrictive way (70). Thus, it was difficult to understand the limited bactericidal effect of ampicillin-bound nanospheres. The most probable explanation is to be found in the resistance mechanism of *S. typhimurium* involving the inhibition of the phagosome–lysosome fusion (71), which lets some bacteria in phagosomes free of nanospheres. If this proposed hypothesis (inhibition of phagosome–lysosome fusion) is correct, the dramatic efficiency observed in vivo should rather be due to the specific targeting of the infected tissues (rich in reticuloendothelial cells), than to an efficient intracellular targeting as it could be supposed.

In order to eliminate both dividing and nondividing bacteria, a fluoroquinolone antibiotic, ciprofloxacin, has been associated with PIBCA and PIHCA nanospheres. In an animal model of persisting *Salmonella* infection, although an effect on the early phase of the infection was observed, neither free nor nanosphere-bound ciprofloxacin was able to eradicate truly persisting bacteria (72).

Since they accumulate in the MPS, nanospheres hold promise as drug carriers for the treatment of visceral leishmaniasis (73). Thus, it has been shown that PIHCA nanospheres can be used as a carrier of primaquine whose activity was increased 21-fold against intracellular *Leishmania donovani* when associated with nanospheres (74). A part of the activity was attributed to the fact that phagocytosis of nanospheres led to the induction of a respiratory burst, which was more pronounced in infected than in noninfected macrophages (74). Dehydroemetine is

also one of the drug candidates for this treatment but has some side effects involving the heart, which were reduced after linkage with nanospheres (75).

Application to the treatment of cancer

When given intravenously, anticancer drugs are distributed throughout the body as a function of the physicochemical properties of the molecule. A pharmacologically active concentration is reached in the tumor tissue at the expense of massive contamination of the rest of the body. For cytostatic compounds, this poor specificity raises a toxicological problem, which presents a serious obstacle to effective therapy. The use of colloidal drug carriers could represent a more rational approach to specific cancer therapy. In addition, the possibility of overcoming multidrug resistance might be achieved by using cytostatics-loaded nanospheres.

The antitumor efficacy of doxorubicin-loaded nanospheres was first tested using the lymphoid leukemia L-1210 as a tumor model. In this study, one intravenous injection of doxorubicin-loaded PIBCA nanospheres was found to be more effective against L1210 leukemia than when the drug was administered in its free form following the same dosing schedule (76). Although the increased life span (ILS %) of mice injected with doxorubicin-loaded PIBCA nanospheres was twice as high as the ILS % for free doxorubicin, there were no long-term survivors.

The effectiveness of doxorubicin-loaded PIHCA nanospheres against L1210 leukemia was even more pronounced than that of doxorubicin loaded onto PIBCA nanospheres. The drug toxicity was markedly decreased when it was bound to this sort of nanospheres, so that impressive results were obtained with this formulation at doses for which the therapeutic efficiency of free doxorubicin was completely masked by the overpowering toxicity of the drug (76). Furthermore, preliminary experiments suggested that one i.v. bolus injection of doxorubicin-loaded nanospheres was more active, in L1210-bearing mice, than perfusion of the free drug for 24 h.

The superiority of doxorubicin targeted with the aid of poly(alkylcyanoacrylate) nanospheres was later confirmed in a murine hepatic metastases model (M5076 reticulosarcoma) (77). Irrespective of the dose and the administration schedule, the reduction in the number of metastases was much greater with doxorubicin-loaded nanospheres than with free doxorubicin, particularly if treatment was given only when the metastases were well established. The improved efficacy of the targeted drug, as clearly confirmed by histological examinations, shows that both the number and the size of the tumor nodules were lower when doxorubicin was administered in its

nanoparticulate form (77). Furthermore, liver biopsies of animals treated with the nanosphere-targeted drug showed a lower cancer cell density inside tumor tissue. Necrosis was often less widespread with the nanosphere-associated drug than in the control group and the group treated with free doxorubicin.

Studies performed on total homogenates of livers from both healthy and metastases-bearing mice showed extensive capture of nanoparticulate doxorubicin by the liver; no difference in hepatic concentrations was noted between healthy and tumor-bearing animals (77). In order to elucidate the mechanism behind the enhanced efficiency of doxorubicin-loaded nanospheres, doxorubicin measurements were made in both metastatic nodules and neighboring healthy hepatic tissue. This provided quantitative information concerning the drug distribution within these tissues (78). During the first 6 h after administration, the exposure of the liver to doxorubicin was 18 times greater for nanosphere-associated doxorubicin. However, no special affinity for the tumor tissue was detected and the nanospheres were seen by electron microscopy to be located within Kupffer cells (macrophages). However, at later time-points, the amount of drug in the tumor tissue increased in nanosphere-treated animals to 2.5 times the level found in animals given free doxorubicin. Since uptake of nanospheres by neoplastic tissue is unlikely, this increase in the doxorubicin concentration in tumor tissue probably resulted from doxorubicin released from healthy tissue, in particular Kupffer cells. Hepatic tissue could play the role of drug reservoir from which prolonged diffusion of the free drug (from nanospheres entrapped in Kupffer cell lysosomes) toward the neighboring malignant cells occurs.

This hypothesis raises the question of the long-term effect of an 18-fold increase of doxorubicin concentration in the liver. Although toxicological data have shown that doxorubicin-loaded nanospheres were not significantly or unexpectedly toxic to the liver in terms of survival rate at high doses, body weight loss, and histological appearance (79), this possibility should be borne in mind, especially since a temporary depletion in the number of Kupffer cells, and hence the ability to clear bacteria, was observed in rats treated with doxorubicin-loaded liposomes (80). A systematic study using unloaded poly(alkylcyanoacrylate) nanoparticles confirmed a reversible decline in the phagocytic capacity of the liver after repeated dosing, as well as a slight inflammatory response (81, 82). Nanoparticle-associated doxorubicin also accumulated in bone marrow, leading to a myelosuppressive effect (83). However, this tropism of carriers might be useful to deliver myelostimulating compounds such as granulocyte colony stimulating factor to reverse the suppressive effects

of intense chemotherapy (84). Nanospheres are also captured by splenic macrophages (85). In this study, the spleen architecture was shown to play a role in the localization of the nanospheres: in mice, uptake was mainly observed in metallophilic macrophages of the marginal zone whereas in rats, which have sinusoidal spleens similar to that of humans, particles were found in the red pulp macrophages.

On the other hand, alteration of the drug distribution profile by linkage to nanospheres can, in some cases, considerably reduce the toxicity of a drug because of reduced accumulation in organs where the most acute toxic effects are exerted. This concept was indeed illustrated with doxorubicin, which displays severe acute and chronic cardiomyopathy. After intravenous administration to mice, plasma levels of doxorubicin were higher when the drug was adsorbed onto nanospheres and at the same time the cardiac concentration of the drug was dramatically reduced (86). In accordance with the observed distribution profile, doxorubicin associated with nanospheres was found to be less toxic than free doxorubicin (78).

The ability of tumor cells to develop simultaneous resistance to multiple lipophilic compounds represents a major problem in cancer chemotherapy. Cellular resistance to anthracyclines has been attributed to an active drug efflux from resistant cells linked to the presence of transmembrane P-glycoprotein, which was not detectable in the parental drug-sensitive cell line. Drugs, such as doxorubicin, appear to enter the cell by passive diffusion through the lipid bilayer. Upon entering the cell, these drugs bind to P-glycoprotein, which forms transmembrane channels and uses energy from ATP hydrolysis to pump these compounds out of the cell (87). To solve this problem, many authors have proposed the use of competitive P-glycoprotein inhibitors, such as the calcium channel blocker verapamil, which are able to bind to P-glycoprotein and to overcome pleiotropic resistance. However, since the adverse effects of verapamil are serious, its clinical use to overcome multidrug resistance is limited.

During the past few years, many studies have been devoted to evaluating the antitumor potential of carrier-drug complexes (88). The effect of nanospheres loaded with doxorubicin, resistance to which is known to be related to the presence of P-glycoprotein, was evaluated. The cytotoxicity of free-doxorubicin, doxorubicin-loaded PIHCA nanospheres (NP-Doxorubicin) (mean diameter 300 nm), and nanospheres without drug (NP), against sensitive (MCF7) and multidrug resistant (Doxorubicin R MCF7) human breast cancer cell lines was compared (89). MCF7 cells were more sensitive to free-doxorubicin than

Doxorubicin R MCF7 cells with a 150-fold difference in the IC_{50} . No significant difference was observed in the survival rate of MCF7 treated with free-Doxorubicin or NP-doxorubicin. In contrast, for doxorubicin R MCF7, the IC_{50} for doxorubicin was 130-fold lower when NP-doxorubicin were used instead of free-doxorubicin (89). These results indicated that nanospheres provided an effective carrier for introducing a cytotoxic dose of doxorubicin into the pleiotropic resistant human cancer cell line Doxorubicin R MCF7.

Complementary experiments, conducted with other sensitive and resistant cell lines, have confirmed this efficacy of nanospheres (90, 91). Doxorubicin resistance was circumvented in the majority of the cell lines tested, and some encouraging results were obtained in vivo in a P388 model growing as ascites (90). Further studies were undertaken to elucidate the mechanism of action of polyalkylcyanoacrylate nanospheres. The incubation time and number of particles per cell were important factors (92) and, when PIBCA nanospheres were used, doxorubicin accumulation within P388/ADR resistant leukemic cells was increased compared with free drug, although no endocytosis of nanospheres occurred (93). On the other hand, when the less rapidly degradable PIHCA nanospheres were used, reversion was observed in the absence of increased intracellular drug (94). The degradation products of poly(alkylcyanoacrylate) nanospheres [mainly poly(cyanoacrylic acid)] were also able to increase both accumulation and cytotoxicity of doxorubicin, although they were soluble in the culture medium. Hence, the reversion of resistance seems to be due both to the adsorption of nanospheres on the cell surface and to the formation of a doxorubicin-poly(cyanoacrylic acid) ion pair, which facilitates the transport of the drug across the cell membrane (94).

In the light of the results obtained with doxorubicin-loaded nanospheres in the liver metastases model described earlier (77), the role of macrophages as a reservoir for doxorubicin was tested in a two-compartment coculture system in vitro with both resistant and sensitive P388 cells (95). Even after prior uptake by macrophages, doxorubicin-loaded PIBCA nanospheres were able to overcome resistance. However, this reversion was only partial. It was decided to take advantage of the particulate drug carrier offers to associate an anticancer drug and a compound capable of inhibiting the P-glycoprotein. This approach was tested with doxorubicin and cyclosporin A bound to the same nanospheres and was found to be extremely effective in reversing P388 resistance (95). The association of cyclosporin A with nanospheres would ensure that it reaches the same sites as the anticancer drug at the same time and would also reduce its toxic side effects.

As early as 1986, Al Khouri et al. (96) observed that like other colloidal carriers, nanocapsules, administered by the IV route in rabbits, were taken up rapidly by organs of the mononuclear phagocyte system. One application that takes advantage of this uptake concerns nanocapsules of (muramyl tripeptide cholesterol) (MTP-Chol). This immunostimulating agent is able to activate macrophages and induce toxicity toward tumor cells, and would therefore be a useful agent to treat metastatic cancer. The mechanisms by which activated macrophages arrest tumor proliferation include production of nitric oxide and $TNF-\alpha$. It was showed in in vitro models of rat alveolar macrophages and RAW 264.7 mouse monocyte macrophage line that nanocapsules based on poly(D,L-lactide) containing MTP-Chol are more efficient activators than the free drug (97, 98). This action could be due to an intracellular delivery of the immunomodulator encapsulated in nanocapsules after phagocytosis and to an intermediate transfer of the drug to serum proteins (99). This system has also demonstrated its efficiency in vivo; in fact, Barratt et al. (100) reported that antimetastatic effects of nanocapsules contained MTP-Chol in a model of liver metastases. Some antimetastatic activity was also seen after oral administration.

Nanospheres for oligonucleotide delivery

Oligodeoxynucleotides are potentially powerful new drugs because of their selectivity for particular gene products in both sense and antisense strategies. However, using antisense oligonucleotides in therapeutics is a challenge to pharmaceutical technology because of their susceptibility to enzymatic degradation and their poor penetration across biological membranes. Nanoparticulate preparations might be an interesting alternative because of better stability in the presence of biological fluids. In the case of nanospheres made of synthetic polymers [poly(alkylcyanoacrylate), poly(lactic acid)], since oligonucleotides have no affinity for the polymeric matrix, association with nanoparticles has been achieved by ion pairing with a cationic surfactant, cetyltrimethylammonium bromide (CTAB) adsorbed onto the nanoparticle surface (101). Oligonucleotides bound to poly(alkylcyanoacrylate) nanospheres in this way were protected from nucleases in vitro (63) and their intracellular uptake was increased (102). In addition, nanospheres were able to concentrate intact oligonucleotides in the liver and in the spleen (103). Antisense oligonucleotides formulated in this way were able to specifically inhibit mutated Ha-ras-mediated cell proliferation and tumorigenicity in nude mice (104).

This approach has recently been applied to the association of a phosphodiester antisense oligonucleotide directed against the 3' nontranslated region of the PKC α

gene with nanospheres prepared from PIBCA. These nanospheres were able to inhibit PKC α neo-expression in cultured Hep G6 cells (105).

Nanospheres containing oligonucleotides have also been formulated from a naturally occurring polysaccharide, alginate, which forms a gel in the presence of calcium ions. In this case, the oligonucleotides penetrate into the gel matrix by reptation, thus providing a high loading yield and good protection against nucleases (106).

Subcutaneous/Intramuscular Administration

Subcutaneous administration of nanoparticles was achieved mainly for the delivery of peptides and vaccines. It allows slow release of the entrapped drugs therefore reducing the number of administrations, increasing blood half-life of the active drug, and finally, in some cases, reducing side effects.

PIBCA nanospheres were injected subcutaneously to rats. Autoradiographic pictures obtained after using radiolabelled polymer have shown a progressive staining reduction in the muscular tissue suggesting that nanospheres were slowly biodegraded (107). In the same study, nanospheres were found to release a peptide (GRF) in a sustained manner. Comparison of the AUC of free GRF and GRF-loaded nanospheres showed that in addition to the slow release process nanospheres were able to improve the bioavailability of the peptide. This improvement could be attributed to the fact that free administered GRF is very quickly metabolized at the injection site, whereas it is partly protected from massive enzymatic degradation when it is administered associated with nanospheres (107).

A few examples of the use of nanospheres as adjuvant for antigens/allergens delivery were described in the literature. The main advantage of this approach is to design single shot vaccine. In this case the drug carrier has to remain at the site of administration and deliver either continuously or pulsatively the antigen. The use of slowly degradable polymers (PLA, PMMA) is suitable for this application, since peptide or protein release is more adequate. Poly(methyl methacrylate) were first investigated as adjuvants for injectable vaccines (108,109). These nanospheres were claimed to be biodegradable after subcutaneous or intramuscular injection and shown to exhibit very powerful adjuvant properties for a number of antigens. However, the adjuvant properties were shown to be better when the antigen was incorporated during the polymerization process than when adsorbed onto nanospheres (110). When comparing the effect of PMMA with other polymers (polystyrene and 2-hydroxyethyl methacrylate/methyl methacrylate copolymer, HEMA:

MMA), it was also demonstrated that a decrease in particle size and an increase in the hydrophobicity of nanospheres increased the antibody response after immunization against influenza whole and split virus, bovine serum albumin, and HIV2 split virus (111–113).

Oral Route

There are numerous reports showing that uptake and translocation of nanoparticles and microparticles take place after oral administration to animals (114–116). Different mechanisms have been proposed to explain the translocation of particulate material across the intestine: i) uptake via Peyer's patches or isolated lymphoid follicles; ii) intracellular uptake, and iii) intracellular/paracellular passage. The uptake of poly(alkylcyanoacrylate) nanocapsules by Peyer's patches has been shown by Damgé et al. (116). When administered in the lumen of an isolated ileal segment of the rat, polyalkylcyanoacrylate nanocapsules were found preferentially over Peyer's patches through which they passed massively and rapidly (116). Nanocapsules were clearly visible in M-cells and in intercellular spaces around the lymph cells. Intracellular uptake of nanospheres has been proposed by Kreuter et al. (117) based on electron-microscopic autoradiographic investigations showing radioactivity into epithelial and goblet cells after oral administration of poly(hexylcyanoacrylate) (PHCA) nanospheres labeled with ^{14}C . The translocation of particles by a paracellular pathway has been evidenced in a study done by Aprahamian et al. (118) using PIBCA nanocapsules. Nanocapsules were filled with an iodinated oil (lipiodol) in order to render them detectable using a scanning electron microscope equipped with an energy-dispersive X-ray spectrometer. When they were administered in an isolated segment of a dog jejunum, they appeared as vesicles associated with intraluminal mucus. Subsequently, they were observed in intravillus capillaries in close contact with red cells or adsorbed to the inner wall of endothelial cells. Among these three mechanisms and according to many studies involving nanoparticles made of other biodegradable and nondegradable polymers, translocation via the uptake in Peyer's patches seems to be the major pathway for a rapid and substantial passage after oral administration of nanoparticles. Although it might exist in certain situations, the passage of particles between the absorptive cells is rather less likely if the barrier of tight junctions has not been disrupted. Although there are abundant reports from various independent workers showing evidence of absorption of particulate systems by the gastrointestinal tract, the oral absorption of

nanoparticles remains a controversial issue. However, even if a more clear estimation of the quantity of absorbed particles is needed as well as a better understanding of the factors affecting particles uptake, it must be concluded that translocation of small sized particles like poly(alkylcyanoacrylate) nanoparticles is possible. The question remains if the extent of particle translocation is compatible with a strategy of drug administration with therapeutic perspectives. This will be discussed below.

Oral Delivery of Peptides and Proteins and Vaccines

Poly(isobutylcyanoacrylate) nanocapsules were shown 10 years ago to be able to encapsulate insulin and to increase its activity as assessed by a reduction of glycemia (119). Several aspects of this phenomenon are surprising: encapsulation of a hydrophilic drug in the oily core of nanocapsules; reduction of glycemia was only obtained with diabetic animals; hypoglycemia appeared two days after a single administration and was maintained for up to 20 days depending on the insulin doses, although the amplitude of the pharmacological effect (minimum level of blood glucose) did not depend on the insulin dose. Damgé et al. (116) and Lowe and Temple (120) suggested that nanocapsules could protect insulin from proteolytic degradation in intestinal fluids, based on the protection of encapsulated insulin, observed in the presence of different enzymes *in vitro*. Later studies showed that insulin did not react with the alkylcyanoacrylate monomer during the formation of nanocapsules and was located within the oily core rather than adsorbed on their surface (27, 121).

The capacity of insulin nanocapsules to reduce glycemia could be explained by their translocation through the intestinal barrier, as suggested by Damgé et al. (116); for example by paracellular pathway or via M cells in Peyer's patches (122). Recently, the use of Texas Red[®]-labeled insulin allowed this translocation to be visualized more readily (123). One hour after oral administration, nanocapsules reached the ileum. The presence of fluorescent areas within the mucosa and even in the lamina propria suggested that insulin-loaded nanocapsules could cross the intestinal epithelium. Although this passage is certainly an important factor, it does not explain the duration of the hypoglycemia. This prolonged action could be due to the retention of a part of the colloidal system in the gastrointestinal tract.

Interestingly, a prolonged hypoglycemic effect was also observed with insulin entrapped in poly(alkylcyanoacrylate) nanospheres when these were dispersed in an oily phase containing surfactant (124). This suggests that some

components of nanocapsules could act as promoters of absorption.

Recently, Damgé et al. (125) showed that the incorporation of octreotide, a somatostatin analogue, in poly(alkylcyanoacrylate) nanocapsules also improved and prolonged the therapeutic effect of this peptide, after administration by the oral route.

Even if the main limitation to oral administration of poly(alkylcyanoacrylate) nanoparticles is that their passage through the intestinal barrier is probably restricted and sometimes erratic, they represent an interesting tool for oral delivery of antigens. Indeed, M-cells appear to be the main site for the uptake of poly(alkylcyanoacrylate) nanoparticles after oral administration (116) and, furthermore, it is generally accepted that limited doses of antigen are sufficient for a mucous immunization. In fact, oral delivery of antigens may be considered as the most convenient means of producing an IgA antibody response. However, it is importantly limited by enzymatic degradation of antigens in the GI tract and, additionally by their poor absorption. Thus, it has been postulated that the use of micro- or nanoparticles for the oral delivery of antigens should be efficient if those systems are able to achieve the protection of the antigenic molecule. Poly(alkylcyanoacrylate) nanoparticles have been shown to enhance the secretory immune response after their oral administration in association with ovalbumin (126). This result was not fully reproduced in the case of poly(acrylamide) nanoparticles loaded with the same antigen. It was postulated that in the case of poly(acrylamide) nanospheres, much of the antigen was located at the surface of the polymer and could have been degraded during its passage through the gut. The relatively high surface concentration of ovalbumin adsorbed onto poly(butylcyanoacrylate) nanospheres may have reduced the ability of the proteolytic enzymes in the gut to gain access to and to degrade the antigen, resulting in a greater antigen availability.

Ocular Delivery

The anatomical structure and the protective physiological process of the eye exert a strong defense against ocular drug delivery. This is the reason why conventional ocular dosage forms exhibit extremely low bioavailability. Limited absorption of the drug through the lipophilic corneal barrier is mainly because of short precorneal residence time due to the tear turn-over, rapid nasolacrimal drainage of instilled drug from the tear fluid, and nonproductive absorption through the conjunctiva. Only a small proportion (1–3%) of the applied drug penetrates the cornea and reaches intraocular tissues. For these

reasons, it is necessary to develop efficient and more acceptable ocular therapeutic systems.

Different strategies can be carried out to improve the precorneal residence time and/or penetration ability of the active ingredient. Among them, one approach consists of using colloidal drug delivery systems such as nanoparticles. Initial studies carried out with nanocapsules, as ocular drug carriers, attempted to increase the penetration of lipophilic drugs into the eye by prolonging the precorneal residence time, as observed with other colloidal systems, liposomes and nanospheres. These studies, which concerned antiglaucomatous agents, such as betaxolol, carteolol, and metipranolol encapsulated in nanocapsules, only showed a reduction of the noncorneal absorption (systemic circulation) leading to reduced side-effects as compared with the free drug (127–129). These systemic side-effects are due to a poor ocular retention of drugs that are directly absorbed into the systemic circulation by conjunctival and nasal blood vessels. In two cases (carteolol and betaxolol), encapsulation in nanocapsules produced an improved pharmacological effect (reduction of intraocular pressure) than produced by free drug and nanospheres (although the penetration of nanocapsules was not tested) and reduced cardiovascular systemic side-effects (127,128). Metipranolol showed the same activity alone and associated with nanocapsules but, as in the case of carteolol and betaxolol, its side-effects were reduced. When betaxolol was used, the nature of the polymer making up the nanocapsule wall was found to be important, and poly(ϵ -caprolactone) was more efficient than PIBCA or poly(lactic-co-glycolic acid) (127).

Calvo et al. (130) explored the mechanisms of interaction of nanocapsules with ocular tissues to better understand the pharmacological responses obtained with antiglaucomatous agents. By confocal microscopy, they showed that poly(ϵ -caprolactone) nanocapsules could specifically penetrate the corneal epithelium by an endocytic process without causing any damage to the cells, in contrast with PIBCA nanoparticles, the uptake of which was associated with cellular lysis (131). These results explained the improved therapeutic effect and the reduction of systemic side-effects as a result of drug loss through the conjunctiva provided by poly(ϵ -caprolactone) nanocapsules by increasing corneal epithelium penetration of lipophilic drugs. Calvo et al. (132) also excluded the influence of the oily inner structure in the activity of the nanocapsules, in the light of the absence of differences in penetration between nanospheres and nanocapsules, in contrast with Marchal Heussler et al. (128) who observed a better therapeutic effect with nanocapsules than with nanospheres. Moreover, Calvo et al. (132) demonstrated with indomethacin-loaded nanocapsules that the colloidal

nature of the carrier was the main factor influencing its ocular bioavailability. The same authors were also interested in the influence of the nature and the charge of the surface of nanocapsules on their physical stability and on their ocular bioavailability (133, 134). They found that coating the negatively charged surface of poly(ϵ -caprolactone) nanocapsules with cationic polymers could prevent their degradation caused by the adsorption of lysozyme, a positively charged enzyme found in tear fluid (133). Moreover, they noticed that a cationic polymer, chitosan, adsorbed on the surface of nanocapsules was able to provide the best corneal drug penetration without any local intolerance as compared to another positively charged polymer. This was achieved by a combination of effects: Penetration of particles into the corneal epithelial cells, mucoadhesion of positively charged particles onto negatively charged membranes, and a specific effect on the tight junctions (134).

This effect of improvement of ocular absorption was also reported by Calvo et al. (135) with the immunosuppressive peptide cyclosporin A. The corneal level of the drug was increased fivefold as compared with an oily solution of the drug owing to a highly loaded nanocapsule preparation, also containing poly(ϵ -caprolactone). The efficacy of this topical formulation has also been observed on a penetrating keratoplasty rejection model in the rat (136). Le Boulrais et al. (137) also proposed an alternative preparation of cyclosporin nanocapsules based on poly(alkylcyanoacrylate) dispersed in poly(acrylic acid) gel able to drastically reduce toxicity of poly(alkylcyanoacrylates) on the cornea and to promote absorption of the drug.

OPTIMIZATION METHODS

Gareth A. Lewis

Sanofi-Synthelabo, Chilly Mazarin, France

INTRODUCTION

What Is Optimization?

Optimization of a formulation or process is finding the best possible composition or operating conditions. Determining such a composition or set of conditions is an enormous task, probably impossible, certainly unnecessary, and in practice, optimization may be considered as the search for a result that is satisfactory and at the same time the best possible within a limited field of search. Thus, the type and components of a formulation may be selected, according to previous experience, by expert knowledge (possibly using an expert system), or by systematic screening as described later. Then the relative and/or total proportions of the excipients are varied to obtain the best endpoint, or a process is chosen, and a study is carried out to determine the best operating conditions to obtain the desired formulation properties. Both of these are optimization studies. This article concentrates on statistical experimental design-based optimization.

Screening, Factor Studies, and Optimization

Systematic screening and factor influence studies are closely related to optimization, being often sequential stages in the development process and involving statistical experimental design methods. Screening methods are used to identify important and critical effects, for example, in the manufacturing process. Factor studies are quantitative studies of the effects of changing potentially critical process and formulation parameters. They involve factorial design and are also quite often referred to as screening studies; however, the resulting relationships have just as often been used for optimization.

The type of study carried out will depend on the stage of the project. In particular, experimental design may be carried out in stages, and the experiments of a factor study may be augmented by further experiments to a design giving the detailed information needed for true optimization. It cannot be stressed too highly that the quality of a statistically designed experiment depends on the choice of experimental run with respect to an a priori model, and

this quality can and must be assessed before starting the experiments.

Brief Historical Review

Statistical methods for screening, factor studies, and optimization have been available for a long time: factorial designs since 1926 (1); screening designs since 1946 (2); and the central composite design for response surface optimization, was introduced by Box and Wilson, in 1951 (3). Their use started to be described in the pharmaceutical literature from the early 1970s, but it was only from approximately 1988 that there was a sudden increase in the number of published articles, and the numbers have continued to rise. A conception or presupposition of the difficulty or complexity of experimental design had to be overcome. The change has been attributed of course to a great extent to the availability of computing power and of relatively inexpensive high-performance software that allows previously difficult or advanced methods to be applied. In particular, much attention is now being given to robust processes and formulation, and there are developments in treating nonlinear and highly correlated responses (4).

Methods for Optimization

There are four primary methods. First, there is the statistically designed experiment, in which experiments are set up in a (normally regular) matrix to estimate the coefficients in a mathematical model that predicts responses within the limits of formulation or operating conditions being studied. This is generally the most powerful method, provided the experimentation zone has been correctly identified, and is the subject of most of this article.

Second, the direct optimization method, the best known being the sequential simplex, is a rapid and powerful method for determining an experimental domain, best combined with experimental design for the optimization itself.

Third, there is the one-factor-at-a-time method in which the experimenter varies first one factor to find the best value, then another. Its disadvantages are that it cannot be

used for multiple responses and that it will not work when there are strong interactions between factors.

Finally, the nonsystematic approach in which the knowledge and intuition of the developer allow him to improve results, changing a number of factors at the same time is often surprisingly successful in the hands of a skilled worker. Where he is less skilled or less lucky, he can waste a remarkable amount of time and resources.

The use of artificial intelligence and expert systems is treated elsewhere in this work.

SCREENING

Obtaining a Formulation Suitable for Optimization

Once the dosage form has been selected, the excipients must be identified, their choice often limited by practical considerations of time and resources determined by patents, company practice, or according to expert knowledge. However, it may be possible or necessary to test a number of different excipients for each function, for example, several diluents, lubricants, binders. This approach has proved useful in drug–excipient compatibility testing in which protoformulations are set up according to a statistical screening design to assess stability and compatibility.

Here the *factor* is the excipient's function. This can be set at different levels, the level being the excipient itself. So the factor may be "binder," and the levels are, for example, HPMC, povidone, polyvinylacetate, and no disintegrant present. A mathematical model relates the response (in this case, degradation) to composition. It includes variables corresponding to each factor with

(qualitative) levels corresponding to each excipient. Plackett and Burman (5) described designs suitable for treating this kind of problem. Designs with the factors at only two levels are widely used. However, there are other designs at 3, 4, and 5 levels as well as asymmetric designs derived from them in which the various factors take a different number of levels (5, 6).

It is assumed that there are no *interactions* between factors; that is to say, the effect of a given excipient on stability does not depend on what other excipients are found in the formulation. (The same reasoning applies to other kinds of factors or responses.) This can only be an approximation; however, if it should be necessary to take interactions into account, many more experiments would be needed, and it would probably be necessary to limit the number of levels for each factor to two for the number of experiments to be manageable.

The choice of excipients may be considered a qualitative optimization, their quantitative compositions not having yet been optimized. This and the fact that the process used will most likely be on a small laboratory scale may affect the choice of excipients. However, it is in most circumstances an unavoidable limitation.

An example of such a qualitative screening is shown in Table 1. This is an experimental design for testing the compatibilities of experimental drug (at two concentrations) with a number of number of excipients. The samples, which were wet granulated, were stored for 3 weeks at 50°C/50% relative humidity. The results are also given in Table 1. The mean degradation level was high, at 6.2%, indicating a fairly unstable drug. The effects of each excipient were calculated by linear regression, or, because the design is *orthogonal*, by linear combinations of the responses, and plotted in Fig. 1. There, the

Table 1 Experimental design and plan for granulated protoformulations

7	Phosphate	NaSG	Mg stearate	HPMC	0.25	2.49
8	Mannitol	NaSG	Mg stearate	Povidone	1.0	4.79

^aCroscarmellose sodium.

^bMicrocrystalline cellulose.

^cCalcium hydrogen phosphate.

^dSodium starch glycolate.

If the factors are quantitative, they are set at their extreme values. Thus, if the factor is *granulation time*, and the possible range is 1.5–7 min, the normal values tested are 1.5 min and 7 min. They are expressed in terms of dimensionless *coded variables*, normally taking values -1 and $+1$. Thus, on transformation to the coded variable x_1 , 1.5 min corresponds to $x_1 = -1$, and 7 min corresponds to $x_1 = +1$.

If the factors are quantitative, they may take any number of levels. Only two-level designs are described here. Qualitative levels are set arbitrarily at the coded levels. If, for example, the screening method was one of the factors tested, wet screening could be set at -1 and dry screening at $+1$ (or vice versa).

Quite wide limits are generally chosen for screening quantitative factors. They are then often narrowed for more detailed quantitative study of the influence of factors where interactions between factors then are taken into account and for determining a predictive model for optimization.

The designs, proposed by Plackett and Burman in 1946 (2), comprise experiments in multiples of four. They will allow screening of up to one less factor than the number of experiments. Those with 2^n experiments (4, 8, 16, 32 H) are also fractional factorial designs. The nonfactorial designs have particular properties and complex *aliasing*, which has been held to make their interpretation difficult but also gives them certain advantages over the fractional factorial designs. The 12-experiment design, shown in coded variables (Table 2), is such a design, and is useful for about 7–11 factors.

The structure of the design is shown clearly in the table because the experiments are in their standard order. However, they should be carried out in a random order, as should all the designs described here, as much as is practicable.

The coefficient β_i is the *effect of the factor X_i* , and is equal to half the average change in the response y when the level of the factor is changed from $x_i = -1$ to $x_i = +1$. It is estimated (as b_i) in the Plackett–Burman design by subtracting the sum of the responses for experiments for which $x_i = -1$ from those for which $x_i = +1$ and dividing by the number of experiments. Important and unimportant effects can then be identified according to their absolute values. (Determining active factors from the results of a factorial design are shown later.)

Use of results of a screening design

Estimation of the effects allows influential or possibly influential factors to be identified. Noninfluential factors (small effects) will not require further study. They may be set at their midpoints, at their most economical values

(e.g., a short mixing time), or at their apparently best value even if the measured effect is apparently nonsignificant.

After elimination of these noninfluential factors, there may still be too many factors to optimize in terms of the resources available (time, raw material, operators, availability of equipment, etc.). Generally, these less influential factors are kept constant, equal to their best level and the remainder optimized. In more complex situations, it is advisable to carry out a more detailed study between the screening and optimization (response surface studies). This could be a completion of the screening study by means of a complementary foldover design (3, 7) or by a separate quantitative study to allow individual effects of the factors and/or their binary interactions to be calculated separately (shown in factorial designs, later).

All these studies on the process are generally done after the optimization of the formulation. However, because the effects of formulation and process changes are not generally independent, it may become necessary to carry out some sort of process study at the same time as the formulation optimization.

QUANTITATIVE PROCESS STUDIES USING FACTORIAL DESIGNS

Purpose

Whereas the purpose of a screening study is to determine which of a large number of factors have an influence on the formulation or process, that of a factor study is to determine quantitatively the influence of the different factors together on the response variables. The number of levels is usually again limited to two, but sufficient experiments are carried out to allow for *interactions* between factors.

Two-level full factorial designs

The simplest such designs are the 2^k full factorial designs, in which the experiments are all the 2^k possible combinations of two levels of k factors variables. Therefore, they consist of 4, 8, 16, 32, 64 H experiments for 2, 3, 4, 5, 6 H factors. Examples are given in Table 3 of the 2^2 , 2^3 , and 2^4 designs (each enclosed at the right and below by the solid lines). Thus, lines 1–4 of columns 1 and 2 show a 2^2 design for two factors, and lines 1–16 of columns 1–4 a 2^4 design for four factors.

The design is transformed into an experimental plan (with the natural or experimental values of the factor variable at each level $-/+1$). The mathematical model associated with the design consists of the *main effects* of each variable plus all the possible *interaction effects*,

Table 3 Some full and fractional factorial designs for two to five factors^a

	X_1	X_2	X_3	X_4	X_5	Response
1	-1	-1	-1	-1	1	189

interactions between two variables, but also between three and four factors and, in fact, between as many as there are in the model. However, although two-factor interactions are important, three-factor interactions are normally far less so. Higher-order interactions are invariably ignored and the values determined for them attributed to the random variation of the experimental system.

Determining Active Factors from the Results of a Factorial Design

We take the four-factor model as an example. The complete synergistic mathematical model consists of the constant term, four main variables (β_1x_1 H β_4x_4), six interactions between two factors ($\beta_{12}x_1x_2$, etc.), four interactions between three factors ($\beta_{123}x_1x_2x_3$, etc.) and one between four factors. The last five of these are not generally expected to be important. The model is thus:

$$y = \beta_0 + \beta_1x_1 \dots + \beta_{12}x_1x_2 \dots + \beta_{123}x_1x_2x_3 \dots + \beta_{1234}x_1x_2x_3x_4 + \varepsilon$$

The effects (coefficients) β_i in the model are estimated, usually by multilinear regression. The values obtained b_i are estimates because of the random experimental error (represented by ε in the equation). The next step is to decide which of the 15 effects calculated are *active* or important.

There are a number of ways of doing this. If the experiments have been replicated, ANOVA will reveal which effects are statistically significant. Otherwise, we rely on the fact that most of the effects are probably small and distributed randomly about zero. Thus, we look for the effects with the largest absolute values that stand out from the others (6). Making a normal probability plot of the distribution of their values is a widely used method.

The responses are usually treated separately; however, when there are a number of more or less correlated responses being studied, appropriate combinations (principal components) may be analyzed instead of the original responses (9).

Once the important effects have been identified, a simplified model can be written. If an interaction term has been identified, the corresponding main effects should also be included in the model even if they are not all found active. Thus, if the interactions between the factors X_1 and X_2 and the main effect of the factor X_1 are active, b_2x_2 should be included in the model as well as b_1x_1 and $b_{12}x_1x_2$.

Two-Level Fractional Factorial Designs

The number of experiments needed to study five or more factors in a full factorial design is large, and to determine the main effects and their interactions, a fraction of the full design is often sufficient. These are $2k-r$ fractional factorial designs, where $r = 1, 2, \text{H}$ for the half, quarter, etc. fractions. An example of a half-factorial design for five factors (2^{5-1}) is given in Table 2 (the entire table). Note that the first four columns are the same as the four factor, full-factorial design, and the column for the fifth factor is constructed by multiplying the first four columns together. Methods for constructing such designs and their limitations are described in many textbooks (5–7).

Evidently, for the 2^{5-1} design, the 16 triple and higher interactions are not determined. In fact, they are confounded with the calculated effects. Thus, the estimate of the interaction between factors one and two includes the triple interaction between the other three factors. Because the latter is assumed negligible, this does not usually matter.

Menon et al. studied the formation of pellets by fluid-bed granulation using this design (8). The five factors investigated were (X_1), the binder concentration; (X_2), the method of introducing it (dry or solution); (X_3), the atomization pressure; (X_4), the spray rate; and (X_5), the inlet temperature. Particle sizes of the resulting particles are shown in Table 3.

The coefficients of the model are calculated by linear regression (the logarithm of the particle size was used

Fig. 2 Calculated effects form a two-level factorial design. Those to the left and right of the line are considered active. (From Ref. 8.)

here) and then plotted as a cumulative distribution of a normal plot (Fig. 2). The important coefficients are those that are strongly positive or negative, for example, the spray rate b_4 and the interaction between atomization pressure and inlet temperature b_{35} . Others not identified on the diagram are not considered significant and could well be representative mainly of experimental error. The equation can thus be simplified to include only the important terms. However, if interactions are included, their main effects should be included also, even if they are small. Here, we have:

$$y = \beta_0 + \beta_1x_1 + \beta_2x_2 + \beta_3x_3 + \beta_4x_4 + \beta_5x_5 \\ + \beta_{13}x_1x_3 + \beta_{14}x_1x_4 + \beta_{15}x_1x_5 + \beta_{35}x_3x_5$$

Information That Can Be Obtained

The significant main effects are identified and also quantified. Thus, increasing the spray rate over the range studied will give an increase in the log(particle size of twice 0.24, representing a more than threefold increase. However, it can be seen that there is an interaction with the binder concentration; that is, the effect of spray rate depends on the amount of binder in the formulation. The effects of increasing spray rate are shown in Fig. 3 for both high and low levels of binder; the effect of spray rate is much greater at high levels of binder.

However, the effect of binder also interacts with two other factors, the atomization pressure and the inlet

Fig. 3 Calculated effects from a two-level factorial design. Interaction diagram for spray rate and % povidone on particle size (logarithmic scale).

temperature. Thus, the individual variables cannot be considered separately.

Note also that there is a great deal of information often hidden in large designs (16 or more experiments), and, in particular, indications on factors affecting the robustness of a process may sometimes be extracted (see the last section).

Use of Center Points

In both screening and factor-influence studies in which the factor is quantitative, it is tempting to interpolate between the upper and lower limits. This is useful if only to find a more restricted zone for further study. However, in the case of a screening study, the limits studied are often so wide that it would be most unlikely for the estimated model to be accurate enough for prediction, and there is also likely to be curvature of the response surface over the experimental domain. Such attempts are less risky for the more detailed factorial studies, but even then, they should be used with caution.

Adding center points (experiments at the center of the domain, coded co-ordinates 0, 0, 0 is useful for factorial and screening experiments), even though they do not enter into the calculation of the model equation because:

1. They are often a priori at or near the most interesting conditions;
2. They allow identification of curvature in the responses (by comparing calculated with measured responses);
3. If they are replicated, the experimental reproducibility may be assessed; and
4. They may allow extension of the experiment at a subsequent stage to a central composite design for modeling of response surfaces (shown later).

EXPERIMENTAL DESIGNS FOR PROCESS OPTIMIZATION (INDEPENDENT VARIABLES)

In this section, we look at methods of obtaining a mathematical model that can be used for qualitative predictions of a response over the whole of the experimental domain. If the model depends on two factors, the response may be considered a topographical surface, drawn as contours or in 3D (Fig. 4). For more factors, we can visualize the surface by taking “slices” at constant values of all but two factors. These methods allow both process and formulation optimization.

Mathematical Models

The design used is a function of the model proposed. Thus, if it is expected that the important responses vary relatively

Fig. 4 Central composite design for three factors. The factorial points are shaded, the axial points unshaded, and the center point(s) filled.

little over the domain, a first-order polynomial will be selected. This will also be the case if the experimenter wishes to perform rather a few experiments at first to check initial assumptions. He may then change to a second-order (quadratic) polynomial model. Second-order polynomials are those most commonly used for response surface modeling and process optimization for up to five variables.

Examples of polynomial models are a first order model for five factors:

$$y = \beta_0 + \beta_1x_1 + \beta_2x_2 + \beta_3x_3 + \beta_4x_4 + \beta_5x_5 + \varepsilon$$

and a second-order model for two factors:

$$y = \beta_0 + \beta_1x_1 + \beta_2x_2 + \beta_{12}x_1x_2 + \beta_{11}x_1^2 + \beta_{22}x_2^2 + \varepsilon$$

The coefficients in the models are estimated by multilinear least-squares regression of the data.

Third-order models are very rarely used in the case of process studies and, in any case, third-order terms are only added for those variables where they can be shown to be necessary (i.e., augmentation of a second-order model and the corresponding design). This does not mean that second-order designs are always sufficient, and other methods of constructing response surfaces may sometimes be useful.

Statistical Experimental Designs for First-Order Models

The design must enable estimation of the first-order effects, preferably free from interference by the interactions between factors other variables. It should also allow testing for the fit of the model and, in particular, for the existence of curvature of the response surface (center points). Two-level factorial designs may be used for this (shown earlier).

Important points to note when using a first-order model, with or without interactions, are that:

1. Maximum and minimum values of responses are of necessity predicted at the edge of the experimental domain;
2. The first-order model should normally be used only in the absence of curvature of the response surface. If the experimental values of the center points are different from the calculate values (i.e., there is lack of fit), then the response surface is curved and a second-order design and model should be used; and
3. The experimenter should test for interaction terms between two factors in the model. If interactions seem to be important he should make sure that they are properly identified.

Statistical Experimental Designs for Second-Order Models

The central composite design (Box–Wilson design)

This is the design most often used for response surfaces. It is a combination of a factorial with an axial design (3, 10) with experiments at a distance of $\pm\alpha$ along each axis (thus, the name). It requires a relatively large number of experimental runs, which can be a disadvantage if resources are limited. However, it can be carried out in two stages: the factorial design first then the axial design if the results are satisfactory.

If we wish to study the system by varying the parameters around a point of interest, the domain is a sphere, and the coordinates of axial experiments are outside those of the factorial ones. α is chosen to give the best statistical properties (e.g., constant prediction precision) and lies between 2 and approximately 2.4. The design for three factors, where α is set at 1.682, is shown in Fig. 5 and Table 4.

Center-point experiments must be done as part of both stages. Another advantage is that each factor is at five levels, thus allowing testing of lack of fit and for the possible need for cubic terms in the model.

Fig. 4 shows response surfaces calculated from the data of Senderak et al. (11) obtained using such a design at a constant value of the third factor.

Other standard designs

The central composite design is most often used, however, there are others whose particular properties make them particularly useful. One of these is the Doehlert design, which is part of a continuous hexagonal network (12). It requires slightly fewer experiments than does the central composite design but cannot be set up by augmenting a factorial design.

The design for three factors is shown in Table 5. It can be seen that the hexagonal design for two factors is the first seven rows and the first two columns. Thus, it is possible to add a factor to a design. Another advantage is that because it is part of a continuous network, it allows the experimental domain to be shifted in any direction by adding experiments at one side of the domain and eliminating them at the other (Fig. 6). Vojnovic et al. (13) give an example of its use in granulation.

Hybrid designs are saturated or almost saturated designs; that is, they have only enough experimental

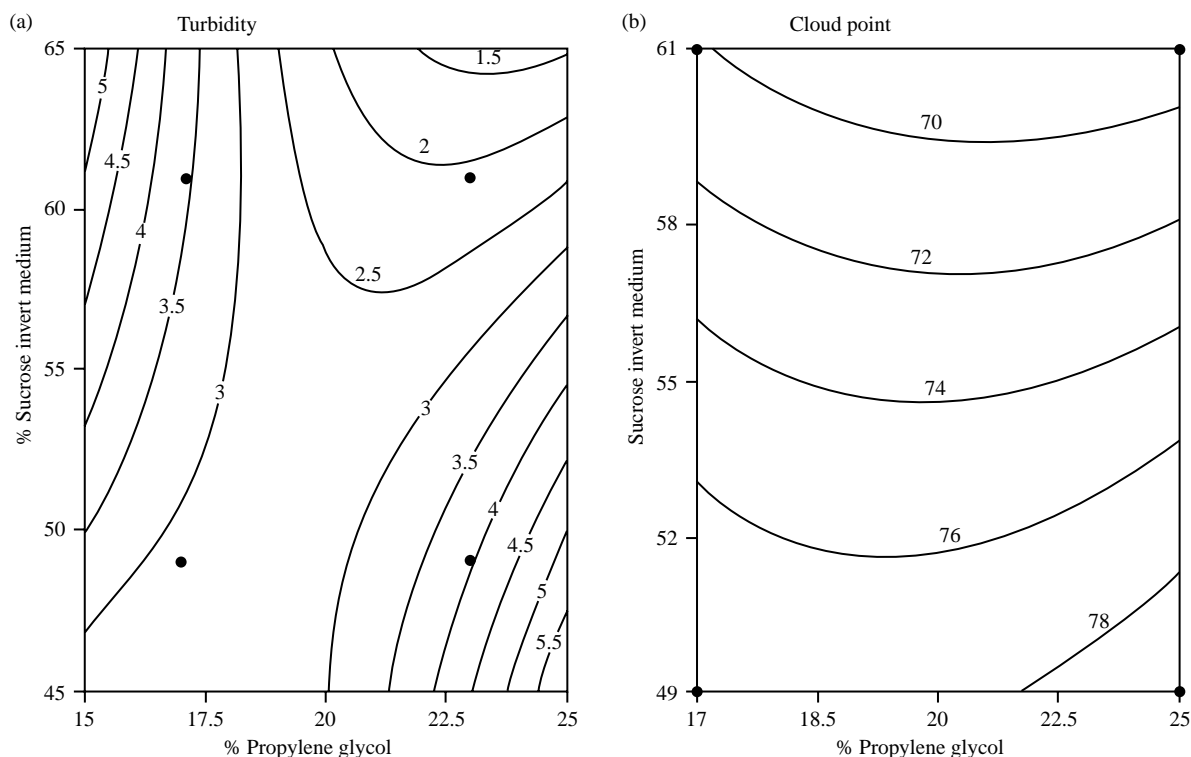

Fig. 5 Contour diagrams of (a) turbidity and (b) cloud point as function of % propylene glycol and sucrose invert medium. (slice taken at constant value of 4.3% polysorbate 80). (From Ref. 11.)

runs to calculate the coefficients of the quadratic model (10 runs for 3 factors 16 runs, for 4 factors, and 28 runs, for 6 factors). They are useful when the responses are not expected to vary enormously but where the quadratic model is esteemed necessary and resources (in possible numbers of experiments) are low (6, 14).

If the experimental region is defined by maximum and minimum values of each factor, then the domain is “cubic.” The central composite design can be applied to such a situation, the axial points being set then at ± 1 , coded values corresponding to the minimum and maximum allowed values. Other designs for the cubic domain are reviewed in Ref. 6.

Mixed and Irregular Domains—D-Optimal Designs

If the experimental domain is cubic and spherical or spherical, the standard experimental designs can normally be used. However, the domain may be irregular in shape as certain combinations of values variable may be excluded a priori for technical reasons or may even have been tried and failed to give a result, or certain factors may be forced to take either fixed discrete but numerical values or may even be qualitative in nature.

There are no classic experimental designs that exist for such circumstances, and a purely empirical approach is required: 1) to postulate a mathematical model that is expected to describe the response, and 2) to then select

from among the many possible experiments a design that will determine the model coefficients with maximum efficiency.

There are various ways of obtaining such a design, by far the most common being based on the exchange algorithm of Fedorov. There are also a number of criteria for describing how good the design is, the D-optimal criterion being the most usual, based on optimization of the overall precision of estimation of the coefficients of the model (6, 15, 16). This method and type of design is extremely flexible because:

Fig. 6 Doehlert design in three dimensions (factors) showing extension to a new experimental domain.

1. It allows experiments within irregular experimental domains;
2. Previous experiments carried out within the experimental domain may be taken into account;
3. Classical designs in which experiments have failed to give a result may be repaired by redefining the domain and finding the best experiments (according to the D-optimal criterion) to replace the experiment(s) which failed;
4. The models may be polynomials with missing coefficients, or even nonpolynomials;
5. The experiments may be carried out in two or more stages, with models of increasing complexity;
6. Further experiments may be added to a D-optimal design to validate the model (lack of fit); and
7. They can be used for mixture models with constraints (see below).

In conclusion, a wide variety of experimental designs is available, allowing the design to be selected according to the problem in question, rather than adapting the experiment to the design.

EXPERIMENTAL DESIGNS FOR FORMULATION OPTIMIZATION (MIXTURE DESIGNS)

Formulations almost invariably consist of mixtures of a drug substance and excipients. Their properties usually depend not so much on the quantity of each substance present as on their proportions. The total comes to 100%, so the number of independent variables is one less than the number of components. This has the effect that the models and the designs have particular properties, and the designs

described above (screening, factor studies, and response surfaces) normally cannot be used. The entire topic of mixture designs is fully described by Cornell (17).

Mathematical Models for Mixtures

Because there is one less independent variables than the number of components, the polynomials take a particular form. For example, for three components, where the response y has a first-order dependence on the fractions x_1 , x_2 , x_3 , because $x_1 + x_2 + x_3 = 1$,

$$y = \alpha_0 + \alpha_1 x_1 + \alpha_2 x_2 + \alpha_3 x_3 + \varepsilon$$

becomes

$$y = \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \varepsilon$$

The variables cannot be varied independently. If there are no upper and lower restraints on the proportions of the components, the domain for three factors can be described as a equilateral triangle whose apices represent the pure components. A four-component mixture is described by a regular tetrahedron. For five components, the equivalent 4D figure must be imagined.

Just as the first-order mixture model has a different form from that for independent variables, so does the second-order design:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_{12} x_1 x_2 + \beta_{13} x_1 x_3 + \beta_{23} x_2 x_3 + \varepsilon$$

The special cubic model describes a certain third-order curvature in the response surface:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_{12} x_1 x_2 + \beta_{13} x_1 x_3 + \beta_{23} x_2 x_3 + \beta_{123} x_1 x_2 x_3 + \varepsilon$$

Mixture Designs and the Simplex Experimental Domain

The equilateral triangle and regular tetrahedron are described above as the domain of a mixture where all possible compositions of the components are allowed for are regular simplexes. (In the remainder of the section, they are referred to as simplexes.) Such circumstances in which there are no composition restraints are rare in formulation. However, if each component is present at a minimum level, and no other constraints are imposed, then the domain is also a simplex.

Designs in this case, primarily attributed to Scheffé (18), are derived very simply. That shown in Fig. 7 for three components is suitable for first-, second-, and partial

Fig. 7 Scheffé central composite design for three factors. Open squares are test points.

third-order models. The latter is the central composite design and is quite commonly used. Test points for checking model fit are also shown.

Constrained Systems and Pseudocomponents

Simplex designs are quite rarely used because such circumstances in which there are no composition restraints are rare in formulation. However, if each component is present at a minimum level, and no other constraints are imposed, then the domain is also a simplex. An example could be of the solubility of a drug being tested in ternary or quaternary mixtures of pharmaceutically acceptable solvents. The single constraint might be that a minimum percentage of water is required. In any case, the experimental domain would be a regular simplex, and standard designs may be used. In the case of solid dosage forms, simplex domains are rarer still. A possible example might be a study of the optimum composition of a diluent in a tablet formulation, the proportions of the active substance and other excipients being held constant. The diluent might consist of a mixture of lactose, microcrystalline cellulose, and starch, and its composition might then be adjusted to obtain optimum tableting properties as well as rapid disintegration and dissolution (for rapid action of the drug after the patient swallows the tablet). Again, standard experimental designs such as the simplex-centroid design may be used.

Constrained Systems and Nonsimplex Designs

Limits in the amounts of excipients present normally lead to the domain taking on an irregular shape. Each component must be present within a given concentration range to fulfill its function. For example, lactose or cellulose may make up most of the amount of a tablet or capsule, whereas magnesium stearate is limited to between 0.5 and 2%. In particular, when there are both upper and lower limits, the space is almost invariably nonsimplex.

Mixture models (such as those of Scheffé) are still useful, especially when there are three or more such excipients with fairly large ranges of variation. In solid formulations, this is often the case for diluents (or fillers) and also for the polymers or waxes incorporated into controlled-release tablets to form a matrix through which the drug diffuses slowly out when immersed in aqueous fluid, i.e., in the gastrointestinal tract.

The experimental designs of nonsimplex experimental regions are D-optimal for the selected model, obtained by an exchange algorithm (19).

Thus, we have the example of the optimization of a sustained-release tablet for which the release rate of a highly water-soluble drug was limited by its diffusion through a matrix. The matrix-forming substance is a cellulose derivative swelling in water (hydroxypropylmethylcellulose) but the diluents microcrystalline cellulose, lactose, and calcium phosphate also have a role. These four components were varied as well as the percentage of drug substance (to have two doses at constant tablet mass), and the experimental domain defined. A D-optimal design was then obtained for a second-order mixture model (using an exchange algorithm), the experiments performed, and the results analyzed by multilinear regression to give response surfaces as contour plots (Fig. 8). The formulation could thus be optimized to give the required drug release profile (6).

It is interesting to note that the work was done in two stages. Initially, experiments were chosen for a first-order mathematical model from the projected second-order design. These were carried out first, to check that there was no problem and that the experimental domain was adequate, before doing the remaining experiments for a predictive model that could be used for optimizing.

Conditions for Independent Variable Designs

If one of the components (for example, a diluent or solvent) is in considerable excess, and the limits for all other components are narrow in comparison, then it can be eliminated from the analysis because its concentration changes little. The concentrations of the remaining

Fig. 8 D-optimal mixture design. (Left) definition of the design space. (Right) Contour plot of mean dissolution time at 25% polymer content. (From Ref. 6.)

components can then be treated as independent variables, and the methods described previously can be applied without using the special considerations for mixtures.

OPTIMIZATION METHODS USING RESPONSE SURFACE METHODOLOGY

Graphical Methods

It is usually relatively simple to find the optimum conditions for a single response that does not depend on more than four factors once the coefficients of the model equations have been estimated, provided, of course, that the model is correct. Real problems are usually more complex. In the case of pellet formation, it is not only the yield of pellets that is important but also their shape (how near to spherical), friability, smoothness, and ease of production. The optimum is a combination of all these.

One possible approach is to select the most important response, the one that should be optimized, such as the yield of pellets. For the remaining responses, we can choose acceptable upper and lower limits. Response surfaces are plotted with only these limits, with unacceptable values shaded. The unshaded area is the acceptable zone. Within that acceptable zone, we may

either select the center for maximum ruggedness of formulation or process or look for a maximum (or minimum or target value) of the key response.

Graphical Optimization of Two Opposing Responses

When there are only two independent factors (including the case of three mixture components), the responses may be plotted on a single graph. Graphics programs that allow plotting of upper and lower allowed limits of the responses, with portions of the diagram where there the responses are outside the limits shaded, are useful because they allow an acceptable zone to be identified very rapidly. An example of graphical analysis for formulation of an oral solution (11) is shown in Fig. 9. The objective was to reduce the turbidity as much as possible and to obtain a solution with a cloud point less than 70°C. A level of invert sucrose as high as possible was preferred (in spite of its deleterious effect on the cloud point). Slices were taken in the propylene glycol, sucrose plane (X_2 , X_3) at different levels of polysorbate, that at 4.3% being shown in the Fig. 9. This can be compared with the response surface in Fig. 5. An optimum compromise formulation is found at approximately 58% sucrose medium, 4.3% polysorbate 80, and 23% polyethylene glycol.

Fig. 9 Superposition of contour plots for turbidity < 3 ppm and cloud point $< 70^\circ$ to determine an optimum region ("slice" at 4.3% polysorbate 80). Compare with Fig. 5 (From Ref. 11.)

The method becomes difficult with four independent continuous factors, and for five or more variables, the method is totally impracticable despite its simplicity. The number of "slices" to be examined is simply too high—up to 125 diagrams to be displayed or plotted. Under such circumstances, the desirability method must be used.

Desirability

Derringer and Suich (6, 20) described a way of overcoming the difficulty of multiple, sometimes opposing, responses. Each response is associated with its own partial *desirability function*. If the value of the response is optimum, its desirability equals 1, and if it is totally unacceptable, its value is zero. Thus, the desirability for each response can be calculated at a given point in the experimental domain. An overall desirability function can be calculated by multiplying all of the r partial functions together and taking the r th root. Evidently, if the desirability for any response is zero at a point, the overall desirability there is also zero. The optimum is the point with the highest value for the desirability. The experimenter should study the contour plot of the desirability surface around the optimum and combine this with contour plots of the most important responses. A

large area or volume of high desirability will indicate a robust formulation or set of processing conditions.

A number of different forms, linear, convex, concave, unilateral, bilateral, are available for the dependence of the partial desirability on the value of the response. Weighting of responses is also possible. The method requires appropriate computer software, but it is a very powerful method of optimization, and with practice, it is relatively easy. It is especially appropriate for four or more factors. McLeod et al. give an example (21).

Limitations of Response Surface Methodology

The approach of using a mathematical model to map responses predictively and then to use these models to optimize is limited to cases in which the relatively simple, normally quadratic model describes the phenomenon in the optimum region with sufficient accuracy. When this is not the case, one possibility is to reduce the size of the domain. Another is to use a more complex model or a nonpolynomial model better suited to the phenomenon in question. The D-optimal designs and exchange algorithms are useful here as in all cases of change of experimental zone or mathematical model. In any case, response surface methodology in optimization is only applicable to continuous functions.

Lately, there has been a great deal of interest in the use of artificial neural networks in many fields, including that of prediction and expert systems, and they are of interest here for the description of response surfaces that have a nonlinear relation to the factor variables (22, 23). In such cases, the response surface may well fit the data better than that calculated from the model estimated by least-squares regression (24).

However, the choice of experiments is still important for the artificial neural network approach, and it is best selected in a regular pattern. The central composite design, in which each factor takes five levels, is a generally a good compromise (24). Great care must be taken not to "overfit," and, in general, more experiments are required than for the classic RSM approach.

SEARCHING FOR A NEW DOMAIN

The Steepest Ascent Method and Optimum Path Methods

Screening and factor studies will sometimes indicate whether, and if so, where we should search for an optimum within the domain being studied. However, if the optimum

(we are considering a single “key” variable here) lies outside the present experiment, then the steepest ascent method comes into its own. The direction of steepest increase of the response in terms of the coded variables is determined, and then experiments are carried out along this line. If a maximum or minimum value (according to the target) is found along this line, the point at which it is found could be the center of a new experimental design for optimization (7). The optimum path method (6, 13) is similar and is used for extrapolating from a second-order design along a curved trajectory.

Sequential Simplex Optimization

Introduction

Unlike the other optimization methods described here, the sequential simplex method for optimization neither assumes nor determines a mathematical model for the phenomena studied.

A simplex is a convex geometric figure of $k+1$ nonplanar vertices in k dimensional space, the number of dimensions corresponding to the number of independent factors. Thus, for two factors, it is a triangle, and for three factors, it is a tetrahedron. The method is sequential because the experiments are analyzed one by one as each is carried out. The basic method used a constant step size (25), allowing the region of experimentation to move at a constant rate toward the optimum. However, a modification that allows the simplex to expand and contract, proposed by Nelder and Mead (26) in 1965, is more generally used. It has been reviewed recently by Waters (27).

Optimization by the extended simplex method

Assume that we wish to optimize a response depending on three to five factors without assuming any model for the dependence other than the domain being continuous. We choose an initial domain and place a regular simplex in it. The experiments for the initial simplex are then carried out and the response measured. In the basic simplex method, an experiment is done outside the simplex in a direction directly opposite to the “worst” point of the simplex. The worst point is discarded, and a new simplex is obtained, the process being repeated. The simplex therefore moves away from the “poor” regions toward the optimum. In the extended simplex method, if the optimum is outside the initial experimental domain, we may leave it rapidly while expanding the simplex for a region with an improved response. As the simplex approaches the optimum, it is contracted rapidly.

Of the experiments of a given simplex let W , N , and B be the “worst” (W), “next worst” (N), and “best” (B) points

Fig. 10 Summary of the expanded simplex method of Nelder and Mead.

of the initial simplex. A new experiment R is carried out opposite point W to give a new simplex reflecting the original one. Depending on the value of the response at R relative to that at W , N , and B , the step size may be expanded to arrive quickly at the region of the optimum, and then be contracted around the optimum. The various possibilities are shown in Fig. 10 for two factors. “ $R > W$ ” means that point R is better than point W , etc.

R replaces W	if : $N \leq R \leq B$ or: $R > B$ and $E \leq B$	Reflection
E replaces W	if : $R > B$ and $E \leq B$	Expansion
C_R replaces W	if : $W < R \leq N$	Contraction (exterior)
C_W replaces W	if : $W > R$	Contraction (interior)

At the end of the sequential simplex, if more detailed information is needed, the experimenter may carry out a response surface study around the supposed optimum.

DESIGNING ROBUST PROCESSES AND FORMULATIONS

Until now, optimization and improvement have been taken as being equal or closer to what is considered most desirable with respect to the mean responses. However, it is also necessary that all units of all batches manufactured fall within those specifications. Apart from variation in the measurement method, all variation is attributed to the manufacturing process and the manufacturing and storage environment.

Taking the traditional quality control approach, any product that is within the specifications will pass and is

considered equally good. However, one might still normally consider that the nearer the response to the target, the better the product. Therefore, the key is to choose a formulation and/or condition that gives a product not only as close as possible to the target, but with as little variability as possible.

The basic concepts and seminal work in this field are from Taguchi (28), who stated that any product whose performance characteristics are different from the target values suffers a loss in quality, which he quantified by a parabolic function. He then classified factors as: 1) *control factors*, which can be controlled under normal operating conditions; and 2) *noise factors*, which are difficult, impossible, or very expensive to control.

The effects and interactions of control and noise factors could be measured by means of an experimental design, and then settings of the control factors would be determined that would minimize the effects of the noise factors.

One problem in such an approach, apart from the difficulty of controlling noise factors, is to know what they are. Examples of possible noise factors are the drug substance and excipient batches, the ambient temperature and humidity, the machine used, the exact granulation time, and the rate at which liquid is added.

The simplest approach in many cases would be to set up an experimental design in the control factors and repeat each experiment many times, hoping for enough natural variation in the noise factors to be able to find conditions to minimize variation. This requires a very large number of experiments, but it is sometimes the only possible way.

Taguchi's solution was to vary the noise factors artificially (28). A design is set up in the control factors, another (factorial) design in the noise factors, and the two multiplied together. The effect of changes in the noise factors can thus be assessed at each point and the variability minimized. This method is preferred to the previous method, but nonetheless, the number of experiments required using Taguchi's *orthogonal networks* is extremely high. Now it is more usual to set up designs in which the number of experiments, although still high, is minimized (29–31) and to find regions where the response is equal to the target value and is at the same time highly insensitive to the noise factors. The design must allow interactions among noise factors, and not only the control factors themselves, but preferably all the terms in the control factor model.

It should be noted that there is a great deal of information "hidden" in large factorial designs ($n = 16$). When analysis shows that only a few factors are significant, the residuals (differences between calculated

and measured values) may be analyzed (32). A small spread of residuals under certain conditions as opposed to others *may* indicate better reproducibility of the process or formulation under these conditions. An example of its pharmaceutical use is presented in the example of Menon et al. (8).

NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY IN PHARMACEUTICAL TECHNOLOGY

Kevin L. Facchine

Thomas M. O'Connell

GlaxoSmithKline, Research Triangle Park, North Carolina, U.S.A.

INTRODUCTION

Nuclear magnetic resonance spectroscopy plays a vital role in essentially all aspects of pharmaceutical development. In the early stages of lead development, NMR is used as a high throughput tool in the analysis of combinatorial libraries and in screening large numbers of compounds for receptor binding. In the synthesis and development of a lead compound, NMR is applied in all manner of structural analyses, including low-level synthetic impurities, degradation products, and metabolites. Advances in sensitivity and experimental design have enabled its use in the analysis of ever more complicated molecules at concentrations down to the nanomolar range. The coupling of NMR with HPLC systems has facilitated the characterization of trace compounds in complex mixtures. Further in-line coupling of NMR with MS systems has provided unprecedented amounts of structural information from a single analysis. In the final stage of drug development, solid-state NMR has been applied to the analysis of bulk drug properties such as polymorphic forms present in drug substances and formulations. The goal of this review is to introduce the reader to the basic principles of NMR and its application to the various stages of drug development. The references are not exhaustive, but have been selected to highlight the key principles and discoveries and point the interested reader toward further study.

PRINCIPLES OF MAGNETIC RESONANCE

The NMR Phenomenon

The nuclear magnetic resonance phenomenon occurs for certain nuclei that possess a magnetic moment μ . When placed in a magnetic field, nuclear moments will align themselves in a discrete number of orientations. The number of orientations is determined by the nuclear spin I , which is a fundamental property of certain nuclei and

has values of 0, 1/2, 1, 3/2, etc. The number of allowed orientations of a nucleus is given by $2I + 1$. The most commonly observed nuclei in NMR, for example, ^1H and ^{13}C , possess a spin equal to $\frac{1}{2}$ and therefore have only two allowed orientations. These two states can be thought of as having the nuclear dipole aligned either with the external magnetic field ($+\frac{1}{2}$, lower energy state) or against the field ($-\frac{1}{2}$, higher energy state). Nuclei such as ^{12}C and ^{16}O , have spin equal to 0 and therefore do not align in a magnetic field and cannot be observed using NMR.

The relationship between the magnetic moment and the nuclear spin is shown in Eq. 1. The proportionality constant γ is known as the gyromagnetic ratio.

$$\gamma = 2\pi\mu/hI \quad (1)$$

The gyromagnetic ratio is directly related to the sensitivity of detection of a particular nucleus. Nuclei with large γ values are more sensitive, that is, easier to detect than those with low values.

NMR experiments involve the application of pulses of radiofrequency (rf) radiation in order to excite nuclei from one energy state to another. The energy separation between these states is given by

$$\Delta E = h\nu = \gamma B_0/2\pi \quad (2)$$

where B_0 is the strength of the applied magnetic field. For the hydrogen nucleus (^1H), or proton as it is commonly referred to, the energy difference corresponds to a radio frequency of around 500 MHz with an external magnetic field of 11.7 T (1 T = 10^4 G). (Often the magnet strength is referred to in terms of the proton resonance frequency, hence an 11.7 T magnet is called a 500 MHz magnet.) Note also from Eq. 2 that γ for a given nucleus determines the relationship between the static magnetic field B_0 and the nuclear magnetic resonance frequency ν . NMR is typically considered to be one of the more insensitive spectroscopic methods due to the fact that the population difference between spin states is about 1 in 10,000 for protons in a 10 T magnetic field. This means that only about 0.01% of the

Table 1 Properties of nuclides important in the study of pharmaceuticals

^aExpressed relative to ¹H = 1 for constant field and equal number of nuclei.

^bAbsolute sensitivity = relative sensitivity × natural abundance.

^c³H is radioactive with a half life of 12.3 years.

(From Lide, D. R. Ed. *CRC Handbook of Chemistry and Physics*, 81st Ed.; CRC Press: New York, 2000, 2001; 9–92.)

sample gives rise to a signal in contrast to other spectroscopies such as IR and UV. Recent advances in commercially available superconducting magnets up to 21.1 T (900 MHz) have greatly increased the sensitivity of NMR experiments.

Table 1 lists some of the important properties of several commonly observed nuclides in the study of pharmaceuticals. Notice that some elements such as hydrogen, have several magnetically active isotopes with very different properties. Interestingly, ³H has the highest sensitivity to detection of any nucleus, but its use is limited by the added complexity of working with a radioactive isotope. The absolute sensitivity listed in the table takes into account the natural abundance of the isotope. Sensitivity can be improved in some studies by the chemical incorporation of magnetically active isotopes such as ¹³C and ¹⁵N.

The basic NMR experiment is most simply described using the vector model shown in Fig. 1. In this model, the bulk magnetization vector represents the slightly greater proportion of the nuclei aligned with the external magnetic field designated as the *z*-axis. The effect of an rf pulse generated perpendicular to the magnetic field is to tip this vector into the transverse (*x*, *y*) plane. In the transverse plane the nuclear spin imparts a precession frequency on each nucleus that is a function of its chemical environment, that is, each chemically distinct type of nucleus has a characteristic precession frequency. The detected signal is the sum of the cosine-modulated amplitudes of each of the precessing spins. Fourier transformation of this signal yields the familiar NMR spectrum. The spectrum contains valuable structural information in the form of chemical shifts, scalar couplings, relative intensities, and linewidths.

Each of these properties will be discussed in the next sections.

Chemical Shifts

When a molecule is placed in a magnetic field, electrons within the molecule shield the nuclei from the magnetic field. The actual magnetic field experienced by a given nucleus is therefore due to both the large external magnetic field, *B*₀, and the effects of nuclear shielding. The chemical shift is defined as the nuclear shielding divided by the applied field. It is always measured from a suitable reference, which is commonly a known compound added directly to the sample. The chemical shift is expressed in parts per million of the resonance frequency of the reference and calculated using Eq. 3

$$\delta(\text{ppm}) = [(\nu_{\text{sample}} - \nu_{\text{ref}}) \times 10^6] / \nu_{\text{ref}} \quad (3)$$

For proton and carbon NMR in organic solvents, the most common reference is tetramethylsilane (TMS), with four sets of equivalent methyl groups whose signal is assigned a value of 0 ppm. For aqueous solutions, trimethylsilylpropionate (TSP) is commonly used, and the trimethyl proton signal is also assigned a value of 0 ppm. The range of chemical shifts experienced by different nuclei is quite variable. The chemical shift range for ¹H is approximately 10 ppm. In contrast, several of the other nuclei listed in Table 1 have much great spectral dispersion. The ¹³C resonances typically cover a spectral window of approximately 250 ppm. For ¹⁵N and ¹⁹F, typical chemical shift ranges are greater than 400 ppm. The wide spectral dispersion experienced by the latter nuclei is very valuable in reducing spectral crowding.

Fig. 1 The basic NMR experiment a) the rf pulse tips the bulk magnetization vector in the the x - y plane; b) the individual spins start to precess according to the frequency determined by their chemical environment; c) the precessing spins are detected along the x -axis as a set of cosine-modulated signals. Fourier transformation of these signals leads to the final spectrum.

Scalar Coupling

Signals in an NMR spectrum can present a characteristic pattern based on through bond interactions with neighboring nuclei. This phenomenon is known as scalar coupling. The proton spectrum of ibuprofen, shown in Fig. 2 has six chemically distinct sets of protons. At each chemical shift, the signals are split into multiple lines due to scalar coupling. This splitting arises from the interactions between neighboring magnetic dipoles (spins). For example, the methyl protons at C_3 of ibuprofen are next to the methine proton at C_2 . At any given time, some of the methine protons will be aligned either with or against the magnetic field. The two orientations of this nucleus result in two contributions to the effective field of the methyl group that leads to the presence of the doublet for the methyl group. The separation between the peaks is known as the coupling constant. The general rule for scalar coupling is that the number of peaks in a multiplet equals $2nI + 1$, where n is the number of neighboring equivalent nuclei and I is the nuclear spin. Thus, the methine proton at C_2 yields a quartet due to coupling to the three equivalent methyl protons. The intensities of each component of a multiplet follow the pattern of Pascal's triangle. This yields peak ratios of 1:1 for a doublet, 1:2:1 for a triplet, 1:3:3:1 for a quartet and so on. In highly crowded spectra the simple $2nI + 1$ rule can break down and more complicated patterns are seen. For more details on the interpretation of these patterns see Chapter 4 of the book by Friebolin (1). The effects of scalar coupling that bring about the multiplicity of a signal provides very useful information regarding the chemical structure.

Scalar coupling data can also yield valuable stereochemical information. The Karplus equation shown below provides a quantitative relationship between the three-bond scalar coupling constant J and the dihedral angle ϕ between two protons (2).

$$J_{\text{vicinal}} = 4.22 - 0.5 \cos \phi + 4.5 \cos^2 \phi \quad (4)$$

In this example, the coefficients above have been empirically optimized for H-C-C-H couplings. It should be noted that the form of Eq. 4 results in two possible dihedral angles for each coupling constant, but stereochemical arguments are often enough to determine a single conformation.

Integration

Another important characteristic of a signal in an NMR spectrum is its integral. Unlike other spectroscopic methods, the detected signal in NMR is directly proportional to the number of nuclei producing it. This

Fig. 2 One-dimensional ^1H spectrum of ibuprofen (5 mg in 600 μl DMSO- d_6 , 25°C, 400 MHz). Peak assignments are given above each set of signals. Expansions of the multiplets for the protons attached to C_2 and C_3 demonstrate the $2nI + 1$ rule of scalar coupling. The integral values are given below the chemical shift axis. Note that the peak for the hydroxyl proton at 11.1 ppm is not shown. Small peaks at 3.3, 2.5, and 0 ppm are from H_2O , DMSO- d_5 , and TMS, respectively.

feature is very useful in the interpretation of NMR spectra since the relative integrals of the signals directly correlate to the relative numbers of nuclei in the molecule giving rise to those signals. The integral values of the ibuprofen signals are displayed below the chemical shift axis in Fig. 2. A caveat in the quantitative interpretation of integrals is that different nuclei require different amounts of time to relax back to equilibrium between pulses. When a signal is not fully relaxed between pulses the amount of magnetization that will be tipped into the x - y plane by the subsequent pulse will be reduced thereby diminishing the integral value. These effects are seen in the slight deviations from the expected integer values in the ibuprofen spectrum. Precise and reliable quantitation of NMR signals therefore requires long delays between pulses. More details of relaxation follow.

Relaxation

After the rf pulse has tipped the magnetization into the transverse plane and the spins begin to precess, nuclear relaxation also begins to bring the signals back to equilibrium along the z -axis. The mechanisms by which energy is transferred to effect relaxation and the rates at which these mechanisms occur are very useful parameters and can be measured experimentally. There are several different relaxation mechanisms, which are more or less important under particular sets of conditions. In solution state studies, the dipole-dipole relaxation mechanism is by far the most important. Any given nucleus in a molecule is surrounded by other dipolar nuclei which are in motion. This motion leads to fluctuating magnetic fields, which can cause nuclear transitions and hence relaxation. Dipolar relaxation is therefore highly dependent upon the molecular motion. The three main forms of relaxation that are important for solution state structural studies are spin-lattice (T_1), spin-spin (T_2), and the nuclear Overhauser effect (nOe). These three mechanisms and their impact on molecular structure analysis are described below.

Spin-lattice relaxation is a process by which the excited spins give up energy to the surroundings (the lattice). This type of relaxation is most efficient when the molecule tumbles at a rate that is very close to the resonance frequency of the nucleus being studied. The rate of tumbling of a molecule is described by the correlation time τ_c . The correlation time can be approximated by

$$\tau_c = 4\pi\eta a^3 / 3kT \quad (5)$$

where η is the viscosity of the solution and a is the radius of the molecule. An approximation of the correlation time

in a typical organic solvent can be derived from the molecular weight (MW), using

$$t_c \approx MW \times 10^{-12} \quad (6)$$

For a proton in an 11.7 T magnet, T_1 relaxation will be fastest when the correlation time is on the order of 500×10^{-6} s. The dependence of T_1 upon correlation time is given in Fig. 3. In typical organic solvents the T_1 minimum is reached for molecules with a molecular weight in the neighborhood of 1–2 kDa.

The T_1 relaxation time is the critical relaxation parameter in obtaining quantitative integrations. For essentially complete relaxation to occur after application of a 90° pulse, a delay time of about $5 \times T_1$ between pulses is recommended, but for nonquantitative analyses, the time can be closer to $1 \times T_1$. In practice, pulses much less than 90° are often used, which allows for more quantitative spectra in less time. For protons on small molecules ($MW < 1000$), typical ^1H T_1 relaxation times range from less than one to several seconds. For ^{13}C , the relaxation times are much longer, in some cases greater than 60 s. The extremely long delays required for accurate ^{13}C integration limit the practical application of quantitative ^{13}C NMR. T_1 times can be readily measured using the inversion-recovery experiment in which the signal intensities are modulated by a series of pulses and delays (1). Curve fitting of the signal intensities as a function of the delays yields the T_1 values.

Spin-spin relaxation is a process in which there is no net loss or gain of energy, but the spins lose phase coherence. The basis of this type of relaxation is the

Fig. 3 Plot of T_1 and T_2 relaxation versus correlation time. The curves have been computed for the dipolar relaxation between two protons separated by 2.0 Å in a magnetic field of 11.7 T.

transfer of energy from one nucleus to another via the fluctuation magnetic fields. As one spin is excited to a higher state, another is relaxed back to the lower state. The net result of these transitions is that the phases of particular types of spins spread out or dephase. As the spins continue to dephase, they will eventually cancel one another resulting in the loss of the signal.

The T_2 time has a critical relationship to the linewidth of the NMR signal at half height ($\Delta\nu$) given by

$$\Delta\nu_{12} = 1\pi T_2^* \quad (7)$$

The term T_2^* is used to denote inclusion of the contributions to T_2 from magnetic field inhomogeneities. When the magnetic field is not totally homogeneous, the small differences in the magnetic field experienced by the same nucleus at different locations in the sample gives rise to slight differences in the precessional frequencies. This leads to the same type of phase coherence loss as the inherent T_2 processes. T_2 relaxation times can be measured using spin-echo experiments designed to eliminate the contributions of field inhomogeneities. These experiments are well described in the book by Friebolin (1).

As with T_1 relaxation, T_2 relaxation has a strong dependence upon the molecular correlation time. Unlike T_1 relaxation, T_2 relaxation does not reach a minimum and then increase, but continues to decrease, as shown in Fig. 3. Therefore large, slowly tumbling molecules have very short T_2 times. This poses a great challenge in the study of large molecules or molecules in the solid state since the lifetime of the signal is very short and the linewidths are very broad.

The nuclear Overhauser effect is the most widely measured of the relaxation phenomena in structural studies. The nOe experiments directly measure the dipole-dipole relaxation between nuclei. The great utility of the nOe is its potential to determine internuclear distances. The magnitude of the nOe is proportional to $(r_{IS})^{-6}$ where r_{IS} is the distance between spins I and S. The nOe effects an increase or decrease in the intensity of a particular signal, based on the spacial proximity of its neighbors and the dynamics of the molecule. For a more rigorous description of the physical basis of the nOe the reader is referred to the excellent text by Neuhaus and Williamson (3).

The dependence of the nOe upon molecular motion is shown in Fig. 4. Notice that both the sign and magnitude of the nOe are a function of the correlation time. An important feature of the nOe is that for molecules in a particular tumbling regime, the nOe passes through zero. This is important for many pharmaceutically relevant compounds since for some molecules with molecular

Fig. 4 Plot of maximum nOe versus $\omega\tau_c$ where $\omega (= 2\pi\nu)$ is the precessional frequency of the nuclei and τ_c is the correlation time. The curve has been computed for a pair of protons separated by 2.0 Å in a magnetic field of 11.7 T.

weights around 1–2 kDa in a viscous solvent like DMSO the tumbling rate can result in nOes very near zero. In this situation no nOe will be observed, irrespective of molecular structure. For these studies, another form of the nOe is more useful. The rotating frame Overhauser effect (rOe) is also function of dipolar relaxation, but occurs under a different set of experimental conditions (4, 5). The advantage of the rOe is that the effect does not pass through zero. The rOe experiments are somewhat more difficult to setup than nOe experiments and quantitative interpretation is more difficult, but they have proven very valuable in the structural analysis of many pharmaceuticals.

NMR TECHNIQUES

NMR has been an integral part of the chemist's analytical toolbox for decades. The most common and fundamental experiment is the one-dimensional (1D) ^1H experiment. The relatively high sensitivity of the ^1H nucleus makes this a very useful start, but for a complex molecule the 1D spectrum can be crowded and often uninterpretable. In these cases more advanced techniques can be used to provide increased resolution and specific types of structural information. In this section we will describe a range of NMR techniques from the simplest 1D experiments to complex multidimensional, multinuclear experiments. The focus of this section will be on the general principles underlying these experiments and their applications to molecules of pharmaceutical interest. Further details on these experiments can be found in the references.

One-Dimensional Experiments

A one-dimensional NMR spectrum provides a wealth of information, which for simple molecules may yield enough detail for complete structural characterization. The ^1H spectrum of a 5 mg sample of ibuprofen shown in Fig. 2 was taken in less than 1 min. Given the relative simplicity of this molecule, all of the ^1H resonances can be assigned by inspection. Full characterization of pharmaceutical molecules often requires that the ^{13}C chemical shifts be assigned as well. However, ^{13}C NMR spectra require much longer acquisition times than ^1H spectra due to the relative sensitivity and low natural abundance (see Table 1). Fig. 5 shows the 1D ^{13}C spectrum of the same 5-mg sample of ibuprofen taken in about 30 min. The broad chemical shift range for ^{13}C yields spectra with typically well-resolved peaks. This spectrum was acquired with the proton decoupler on throughout the experiment, which collapses all of the ^{13}C multiplets into singlets. Additionally the ^1H decoupling provides a signal enhancement of up to 200% due to the ^1H – ^{13}C nOe. [Further details on heteronuclear nOes can be found in Chapter 2 of Ref. (3)]. For relatively simple compounds in which there are ample amounts of sample, the 1D ^1H and ^{13}C spectra can yield unequivocal assignments.

For samples such as natural products, metabolites, and degradation products, the sample amounts are typically far less than the 5 mg used in the example above. In these cases the ^1H spectrum is still a necessity, but it may be impractical to acquire a ^{13}C spectrum. The signal to noise ratio (S/N) for NMR spectra is a linear function of sample concentration, but builds up as the square root of the number of scans. Therefore, if the sample concentration is reduced by a factor of 100, it will take 100^2 times the number of scans to achieve a spectrum with the same S/N .

Spin Polarization Transfer

Several methods of signal enhancement have been developed to help overcome the inherently low sensitivity of important nuclei such as ^{13}C and ^{15}N . These experiments rely on the principle of spin polarization transfer where magnetization on the more sensitive nuclei, usually ^1H , is transferred to the attached nuclei of interest through a specific sequence of pulses and delays. The signal enhancement achievable through polarization transfer is proportional to γ_I/γ_S , where I and S represent the abundant and rare spins, respectively. This corresponds to a factor of 4 for ^{13}C and a factor of 10 for ^{15}N (see Table 1) and can yield dramatic savings in

Fig. 5 ^{13}C NMR spectrum of ibuprofen (5 mg in 600 μl DMSO- d_6 , 25°C, 100 MHz). Peak assignments are given above the signals and refer to the chemical numbering shown in Fig. 2. Note the overlap between C_2 and C_{10} .

acquisition time. Polarization transfer experiments also enable use of faster repetition rates based on the typically shorter T_1 relaxation rates of the protons thereby providing an additional gain in overall sensitivity. Two methods of polarization transfer used in solution NMR are the INEPT (Insensitive Nuclei Enhanced by Polarization Transfer) experiment (6) and the DEPT (Distortionless Enhancement by Polarization Transfer) experiment (7). The latter experiment provides the added feature of spectral editing such that subspectra containing different types of carbons can be obtained or a single spectrum generated where methyl and methine carbon resonances are phased positive and methylene carbon resonances are negative. Quaternary carbons are not observed in these experiments since the signals rely on the transfer of polarization from attached protons.

Two-Dimensional Experiments

As the size and complexity of a molecule increases, the proton NMR spectrum can easily become crowded and very difficult to interpret. Steroids are a common class of compounds of pharmaceutical interest and provide a very good example of spectral crowding. Steroid ^1H NMR spectra typically contain a region between approximately 1 and 4 ppm known as the methylene envelope in which a large proportion of the proton signals reside (8). In this situation, two-dimensional (2D) NMR can be used to spread the signals out into a second dimension providing an invaluable increase in resolution. The simplest of the 2D experiments is the COSY (CORrelation SpectroscopY) experiment. COSY spectra are characterized by two types of peaks, those along the diagonal and crosspeaks located off of the diagonal. The diagonal is effectively a 1D spectrum, and the crosspeaks indicate a scalar coupling relationship between the two resonances at coordinate chemical shifts of the crosspeak. Fig. 6 shows an expansion of the double quantum filtered COSY spectrum of the highly crowded region of dutasteride. The double quantum filtered COSY is a simple modification of the COSY experiment, which, among other benefits, yields narrower diagonal peaks allowing for crosspeaks close to the diagonal to be better resolved (9). Notice that the crosspeaks in the spectrum are characterized by a specific pattern, which contains the scalar coupling information between the correlated protons. COSY spectra can provide both connectivity and scalar coupling constants from highly crowded spectra, although the latter is not always straightforward.

TOCSY (TOtal Correlation Spectroscopy) is another important homonuclear 2D correlation experiment where

correlations arise due to the presence of homonuclear scalar coupling (10). In the standard COSY experiment, crosspeaks appear for spins in which the scalar coupling occurs over typically two to four bonds. In the TOCSY experiment crosspeaks can appear for spins separated by many more bonds as long as they are part of a contiguous network of coupled spins. The correlations are effected by the application of a series of low-power rf pulses termed the spin-lock. The duration of the spin-lock period determines the extent to which the correlations are propagated through the spin system. The TOCSY experiment is a useful complement to the COSY methods for the elucidation of complex structures.

The 2D nOe experiment NOESY (Nuclear Overhauser Enhancement SpectroscopY) provides correlations between nuclei that are close in space. While nOe experiments can be carried out using selective excitation of individual signals, one at a time, to determine the identity of protons proximal to the selected peak, the NOESY experiment enables the determination of nOe information between all spins in one experiment. Cross peaks in a NOESY experiment indicate which protons are close to one another. Typically nOe crosspeaks can be observed for protons less than 5 Å apart in the molecule. Fig. 7 shows the NOESY spectrum of dutasteride with several key correlations highlighted. The results of this experiment enable complete stereochemical assignment of all the protons in the molecule.

Two dimensional experiments can also show correlations between different types of nuclei. These heteronuclear experiments have the advantage that nuclei such as ^{13}C and ^{15}N have much wider chemical shift ranges, and therefore the 2D experiments achieve a tremendous reduction in spectral crowding. The HETCOR (HETeronuclear CORrelation) experiment was the first 2D experiment developed to provide correlations between ^1H and ^{13}C . In this experiment, the magnetization is transferred from a proton to its attached carbon via the one bond scalar coupling in a manner similar to the DEPT experiment. The acquisition parameters can be modified to allow for the correlation of protons to carbons several bonds away by optimizing for the smaller multiple bond heteronuclear scalar coupling constants. The multiple bond correlations can be combined with the single bond correlations to put together the pieces of a molecule for complete structure elucidation or spectral assignment. While it provides important C–H connectivity information, the HETCOR experiment suffers from relatively poor sensitivity resulting from the detection of the carbon signals.

Fig. 6 Aliphatic region of a DQF-COSY spectrum of dutasteride in DMSO- d_6 . Correlations show scalar connectivities between neighboring protons and facilitate proton resonance assignments, which begin with H₅ and are traced throughout the spin system. (See Fig. 10 for structure and numbering scheme.) Complete analysis is complicated by overlapping resonances.

Inverse Detection Experiments

Inverse detection experiments consist of a sequence of pulses and delays that transfer the magnetization from ^1H to the attached X nuclei (typically ^{13}C or ^{15}N) and then back to ^1H for detection. In this way, the experiments maintain a sensitivity level much closer to

a standard ^1H experiment and represent a marked improvement over the HETCOR experiments. The first of these types of experiments was the HMQC (Heteronuclear Multiple Quantum Coherence) experiment (11). Fig. 8 shows the HMQC spectrum of dutasteride. The utility of this experiment is the ability to resolve overlapping proton resonances by spreading

Fig. 7 Aliphatic region of a NOESY spectrum of dutasteride in DMSO- d_6 . Correlations show through space interactions between neighboring nuclei and are used to make relative stereochemical assignments for proton resonances. Correlations between the H₁₈ methyl group and nearby protons on the same side of the steroid ring system are highlighted. (See Fig. 10 for structure and numbering scheme.)

them out over the carbon chemical shift dimension and assign carbon resonances from known proton assignments or vice versa. Some key correlations are highlighted. Note that inequivalent methylene protons are readily identified as they show correlations to the same carbon. This experiment contains exactly the same type of information as the HETCOR, but spectra of

equivalent S/N can be acquired in about one-fourth the time for ^1H - ^{13}C correlations and one tenth the time for ^1H - ^{15}N correlations. Given the inherently low sensitivity of ^{15}N , direct observation of ^{15}N is rarely done, but inverse detection methods have made ^1H - ^{15}N correlations much more facile. A recent review by Martin describes the utility of the ^1H - ^{15}N inverse

Fig. 8 Expansion of the HMQC spectrum of dutasteride in DMSO- d_6 showing heteronuclear correlations used to identify pairs of methylene protons and assign carbon resonances based on proton assignments. The six methylene proton pairs highlighted are readily identified since there are two protons with different chemical shifts correlated to each carbon. (See Fig. 10 for structure and numbering scheme.)

detection experiments in the structural determination of natural products (12).

The HSQC (Heteronuclear Single Quantum Coherence) experiment is another widely used inverse detection experiment (13, 14). It provides essentially the same information as HMQC, but relies on a different sequence

of pulses to effect the transfer of magnetization between ^1H and the heteronucleus. A direct comparison of HMQC and HSQC in the study of a natural product has indicated some advantages of the latter-sequence, which may provide improved sensitivity and narrower crosspeaks for improved resolution (15).

Long range proton connectivities to heteronuclei can also be obtained from inverse detection experiments. A modification of the HMQC referred to as the HMBC (Heteronuclear Multiple Bond Coherence) experiment can be optimized for transfer through multiple bonds based on the value of the multiple bond couplings (16), which is

typically about 8 Hz for a three-bond ^1H - ^{13}C coupling. The HMBC spectrum of dutasteride shown in Fig. 9 illustrates the utility of this experiment for assigning quaternary carbons, connecting isolated spin systems (e.g., H_{18} and H_{19}) to other spin systems in the molecule, and confirming assignments made from the COSY and HMQC spectra.

Fig. 9 Expansion of the HMBC spectrum of dutasteride in $\text{DMSO}-d_6$ showing multiple bond correlations used to assign quaternary carbon resonances. Highlighted are correlations used to assign C_{10} , C_{13} , and the carbonyl resonance C_{20} , which is folded over in the ^{13}C dimension. Other correlations in the spectrum serve to confirm resonance assignments made based on results from the other experiments. (See Fig. 10 for structure and numbering scheme.)

Recent years have seen a great deal of activity in the improvement of HMBC sequences including the accordion type experiments. These experiments are optimized for transfer through a wide range of heteronuclear couplings (e.g., 2–25 Hz) and can provide H–C correlations over two to four bonds. Accordion experiments have found great utility in the assignment of some complex natural products. The details and specific advantages of these experiments has been recently reviewed (17).

For small molecules of pharmaceutical interest, the foregoing array of NMR experiments yield most if not all of the information required to fully interpret the ^1H and ^{13}C NMR spectra and to completely characterize the structure of a molecule. The results of this type of analysis are summarized in Figs. 10 and 11, typical of what is often required for regulatory submissions.

Higher-Dimensional Experiments

There is no limit to the complexity of molecular structures and thus, it is clear that NMR spectra can become ever more complicated. In large molecules such as proteins, the second dimension is often not enough to provide the necessary resolution for facile interpretation. This has led to the development of three-dimensional (3D) experiments (18). In these experiments the resonances are spread out into a third dimension with the spectrum taking the form of a cube. Examples of a heteronuclear 3D experiment include HMQC–COSY and HMQC–NOESY in which the crosspeaks of a COSY or NOESY spectrum are further separated in the third dimension by their respective carbon chemical shifts (19). Four-dimensional (4D) experiments are also frequently used in the study of proteins in which correlations can be made between ^1H , ^{13}C , and ^{15}N in a single (triple-resonance) experiment. These spectra can be visualized as a cube in which each slice through the cube can be expanded into another cube. Protein studies often involve the incorporation of ^{13}C and ^{15}N isotopes into the protein, which greatly increases the sensitivity of the highly time consuming 3D and 4D experiments. An excellent description of higher dimensional experiments and their applications to protein structure elucidation is given in the review by Clore and Gronenborn (20).

Pulsed Field Gradients

One of the most important developments in NMR in recent years has been the application of pulsed field gradients (PFGs) (21). PFGs have long been used in magnetic resonance imaging methods, but only in the last decade has the technology been developed for routine use in high resolution NMR. PFGs consist of an extra magnetic field

applied across the sample in a spatially dependent manner. This imparts a phase shift to a given signal which is correlated to its position in the sample. PFGs have many utilities in high resolution NMR. They can be used to eliminate certain undesired signals by selectively dephasing them. Alternatively, signals can be selected using pairs of gradients in which the first gradient dephases all spins and a second gradient is optimized to refocus only selected spins. The judicious implementation of PFGs in pulse sequences has led to much cleaner spectra with fewer artifacts.

Another important use of PFGs is in the study of diffusion processes. A pair of PFGs of opposite sign separated by a delay time can be used to analyze the diffusion of molecules. If a molecule migrates significantly during the diffusion period, the second gradient will not effectively refocus those spins and the signals for that molecule will become attenuated. The use of PFG diffusion studies in high throughput screening studies will be discussed ahead.

APPLICATIONS OF NMR

The NMR techniques described in the last section provide the foundation for many of the advanced applications of NMR in the pharmaceutical industry. The challenges of this industry have led to the optimization of hardware and experimental design to answer specific questions. Some of the most important questions and the NMR applications that have been developed to answer them will be described in the next sections.

Analysis of Small Sample Quantities

Small volume NMR probes

Samples such as metabolites, degradation products, and natural products may be very laborious to isolate and purify and are often available in only extremely small quantities. The sensitivity of NMR is considered low *vis a vis* other structural methods such as UV, IR, and MS, but the high information content has made increasing the limits of detection a very active and worthwhile pursuit. Sensitivity increases have traditionally been achieved by increasing the sample concentration or the magnetic field strength, but in recent years, optimization of the NMR probe has yielded significant gains. The NMR probe houses the hardware for the delivery of rf pulses and the detection of the NMR signal. Until recently, 5 mm sample tubes with a sample volume of 500–600 μl was the

standard for solution NMR studies. With very small sample amounts this results in a very dilute sample. Commercial NMR probes are now available for sample tubes as small as 1.7 mm with sample volumes down to 30 μ l. Efficient coupling of the NMR detector coil to physically smaller samples has resulted in a more than eightfold decrease in acquisition time over the standard 5-mm NMR sample tube configuration (22). The decrease in sample volumes has been taken even further by Sweedler and coworkers who have recently designed microcoil probes with a 200-nl sample volume (23). Reductions in sample volume provide an effective means to increase sensitivity, but further reductions may be less effective due to difficulties in routinely handling such small samples.

Low temperature probes

Increases in sensitivity can be also achieved by reducing the temperature of the detection coil. This was first demonstrated by Styles and coworkers who obtained substantial increases by operating the coil at cryogenic temperatures (24, 25). Recently an application of high resolution NMR on a natural product has been reported using a probe with rf coils made of high-temperature superconducting (HTS) materials operating at 25 K (26) where an enhancement in signal to noise of 3.5 was obtained over conventional probes. Currently, the HTS probes appear to have limited utility because the geometry of the coils cannot be optimized for standard cylindrical NMR tubes. Using the same idea of reduced temperature rf coil detection, cold probes are now being developed in which standard probe coil materials are cooled. This probe cooling combined with optimization for small sample volumes provides further sensitivity enhancements.

Flow NMR Methods

High-throughput NMR

Advances in parallel synthesis and combinatorial chemistry have given pharmaceutical companies the ability to generate an unprecedented number of compounds. In lead compound optimization efforts, libraries containing hundreds of compounds are often made for which structure validation is often necessary. For the synthetic chemist, high resolution NMR would be the tool of choice for this effort, but the standard method of preparing hundreds of individual NMR tubes for analysis would be prohibitively time consuming. This hurdle has been overcome by the development of flow NMR systems (27), which utilize a specialized flow cell in the probe so that samples can be injected into the NMR without the preparation of

individual sample tubes. HPLC type autosamplers connected to an injector system deliver the sample directly to the flow cell of the probe. In this way, samples in microtiter plates can be analyzed in an automated fashion. After the spectrum is taken, the flow can be reversed and the sample returned to its original location in the plate or diverted to waste. These probes have been optimized in terms of sensitivity to detect small sample quantities from micrograms down to hundreds of nanograms.

LC-NMR

Many of the most important chemical questions in the pharmaceutical industry involve the analysis of complex mixtures. Identification of low-level metabolites and drug substance impurities usually requires high-performance liquid chromatography for the separation of these mixtures or isolation of a compound of interest from a sample matrix. In these analyses, the structural information obtainable for the low-level compounds is limited by the type of detection used. The coupling of HPLC and mass spectrometry has become routine and provides useful molecular weight and fragmentation information, but this is often not enough for complete structure elucidation.

Recently, NMR spectrometers directly coupled with LC systems have become commercially available (28, 29). Spectra can be acquired in either of two modes, continuous or stopped flow. In continuous flow mode the spectrum is acquired as the analyte flows through the cell. This method suffers from low sensitivity since the analyte may be present in the cell for only a brief period of time, but it has the advantage of continuous monitoring of the LC peaks without interruption. Fig. 12a shows a contour plot of the continuous flow NMR analysis of a mixture of vitamin A acetate isomers (30). Fig. 12b shows the spectra taken from slices through the contour plot. These plots highlight the olefinic region of the spectra which provided ample information for the identification of each of the isomers. With very limited sample quantities, the more common method of LC-NMR analysis is stopped flow. Here the analyte peak is parked in the flow cell so any of the standard NMR experiments can be run.

A problem with the coupling of HPLC to NMR is that typical LC solvents give rise to very large background signals. The simplest way to avoid this is by using deuterated solvents, but given the relatively large volumes of solvent necessary, this can be very expensive. Recently developed solvent suppression methods have provided excellent means of reducing the signals from fully protonated solvents. These methods utilize a series of selective pulses along with pulsed field gradients and can simultaneously suppress several solvent signals in the spectrum (31). Another problem can arise when gradient elution methods

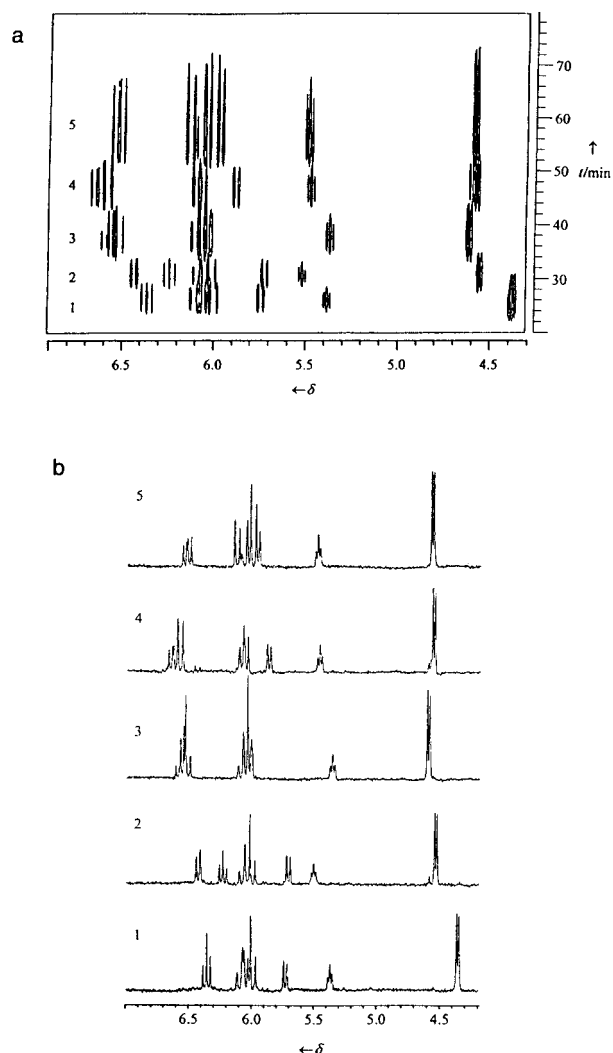

Fig. 12 a) Contour plot of the LC-NMR analysis of a mixture of vitamin A acetate isomers (400 MHz). b) Slices taken through the contour plot showing spectra of the individual components of the mixture. (From Ref. 30.)

are used in the LC separation because the chemical shifts of the solvent resonances can change as the gradient mixture changes. This is addressed by software that can dynamically modify the solvent suppression scheme to keep up with the chemical shift changes of the solvent resonances. Even with fully deuterated solvents for all mobile phase components solvent suppression methods are often still required for the residual protonated solvent signals.

LC-NMR-MS

The combination of LC with analytical methods has been taken a step further with in-line coupling of LC, NMR, and

MS systems to provide maximum information with minimal sample handling (32, 33). This setup yields both structural and molecular mass information from a single HPLC injection. The practical issues of running a mass spectrometer in close proximity to the magnetic field of the NMR provided somewhat of a hurdle to the technique, but this has been recently addressed by actively shielded magnets in which the stray magnetic fields are greatly attenuated by counter acting fields engineered into the magnet. The NMR and MS are typically setup in parallel with the flow split such that a small amount of the sample is sent to the MS and the rest to the NMR flow cell. This provides two sets of synchronized datasets, which facilitates interpretation. This also avoids potential issues of back pressure from the flow at the interface between the NMR and the MS.

NMR Based Screening Methods

Affinity NMR

One of the challenges that arises from the synthesis of combinatorial libraries is the screening of huge numbers of molecules for a desired biological activity. Mixtures of molecules are often screened in a single test which can lead to erroneous results. In some assays the sum of multiple small interactions can lead the screen to give a positive result when in fact no single molecule in the mixture is suitable for further study. A variety of experiments based on NMR have been developed recently that allow for the screening of complex mixtures with no need for physical separation and no risk of false positives from the additive effects of weak interactions. One of the methods for screening mixtures referred to as affinity NMR or diffusion edited NMR can be used to selectively observe only those ligands in a mixture that bind to a receptor molecule (34). The selection process is based on the changes in the diffusion rate of a ligand that occurs upon binding.

Affinity NMR experiments exploit the fact that the diffusion rate of molecules that bind to a receptor molecule will be greatly reduced. As described earlier, a PFG is applied to dephase all of the NMR signals. An equal but opposite PFG is applied after a delay time to refocus only those spins involved in binding to the receptor. Molecules not involved in binding will rapidly diffuse during the delay period between gradients, and their signals will be greatly attenuated. A qualitative ranking of ligand binding can be made based on the observed signal intensities. Although there are certain factors such as exchange phenomena that can complicate the interpretation of diffusion studies [see

Ref. (34)], the relative simplicity and nondestructive nature of diffusion based NMR screening make it a very valuable tool in drug discovery.

Transferred nOe screening

Another form of affinity NMR relies on the transferred nOe (35). As discussed earlier, small rapidly tumbling molecules display positive nOes and large slowly tumbling molecules display negative nOes. Upon binding to a large receptor, a small molecule assumes the correlation time of the receptor and large negative nOes develop. After the molecule dissociates from the receptor, the intensities of the signals remain perturbed by the large negative nOes, but the rapid small molecule tumbling rate yields narrow linewidths. The NOESY sequence can be used in these studies, and the negative nOe signals can be selectively displayed. The sensitivity of this method can be adjusted by varying the ratio of ligand to receptor. Typically, studies have observed the ligand in a 10–20-fold excess that allows these experiments to be carried out with very small amounts of receptor. This is a great advantage of transferred nOe based screening, especially with receptors that are difficult to produce and isolate.

Biomolecular NMR Studies

Protein structure studies

Due to their size and spectral complexity, proteins are among the most challenging molecules for NMR spectroscopy. As discussed earlier, a large number of sophisticated multidimensional, multinuclear NMR methods have been developed for the complete structural determination of proteins. The general procedure for protein structure determination can be summarized as four basic steps. The first step is sequential assignment of all amino acid resonances, using through-bond or through-space experiments. The second step is torsion angle determination using three-bond scalar coupling information. The third step is identification of through space interactions, using nOes. And the fourth step is calculation of the structure based on the structural restraints (nOes and torsion angles) using one or more computational refinement tools (20). This process requires large amounts of data to be acquired for a complete structure elucidation, which can be very time-consuming. Advances in molecular biology have made the incorporation of isotope labels in proteins using microbial systems relatively routine. With ^{15}N and ^{13}C labels the requisite 3D and 4D experiments can often be acquired in a matter of hours

rather than days. Currently it is possible to determine the structures of proteins in the 15–35 kDa range at a resolution comparable to ~ 2.5 Å resolution crystal structures.

Protein–ligand interactions

Solution state NMR experiments that probe the interactions between ligands and receptors have become an important part of the drug development process. When the structure of a protein has been completely determined by NMR, small changes in the chemical shifts of residues in the binding site will occur upon addition of an active ligand. These chemical shift changes are readily observed in $^1\text{H}\{^{15}\text{N}\}$ HSQC spectra acquired using ^{15}N labeled proteins. This method, known as chemical shift mapping, has been used to identify the binding sites of proteins, screen for active ligands, and design and optimize lead compounds.

High-throughput chemical shift mapping studies to screen for active ligands has recently been demonstrated using cryoprobe technology. The increased sensitivity of the cryoprobes enables protein $^1\text{H}\{^{15}\text{N}\}$ HSQC spectra to be acquired using very low protein concentrations. Since the total concentration of added molecules in these studies must be kept at a reasonable level (~ 5 – 10 mM), the use of lower protein concentrations allows for higher ligand concentrations. Hadjuk and coworkers analyzed mixtures of 100 compounds for the presence of tight binding molecules (36). The authors suggest that libraries of more than 200,000 compounds can be tested in less than one month using this strategy.

Structure–activity relationships (SAR) by NMR

A fundamental part of the drug design process is the development of structure–activity relationships. Recently an NMR method has been developed to produce SARs (37). In this method ligands are constructed from building blocks that have been optimized for binding to individual protein sub-sites. In the first step, a library of small organic molecules is screened for binding to a labeled protein. The binding event is detected by the observation of ^{15}N or ^1H chemical shift changes in the $^1\text{H}\{^{15}\text{N}\}$ HSQC spectra for resonances near the binding site. Once a lead molecule is identified, analogs are synthesized to optimize the binding. The process is then repeated to identify ligands that bind to a proximal binding site. Finally the separately optimized ligands are linked together to form a single high affinity ligand. This method was used to design a ligand to the immunosuppressant protein FK506 with an affinity of 19 nM.

SOLID-STATE NMR

A large proportion of pharmaceuticals end up in a solid formulation, so there is a clear need to characterize drugs in the solid state. Many different methods are available to study solid-state drug substances, including IR, Raman and X-ray diffraction, each with its own advantages and disadvantages (38). As in the solution state, solid-state NMR offers a potentially high level of structural information compared to other methods. In this section, a brief review of some of the fundamental differences between solid and liquid state NMR will be given along with some illustrative examples of the role of solid state NMR in pharmaceutical development.

Anisotropy in the Solid State

Simply placing a pellet of solid drug substance in an NMR tube and acquiring a ^1H or ^{13}C spectrum will yield very poor results. The resulting spectrum would typically appear as a collection of highly overlapping signals with linewidths in the thousands of Hertz. The basis for this extreme line broadening is the presence of anisotropic (orientation dependent) effects that are averaged out in solution, but become dominant in the solid state. The most important of these anisotropic effects are the dipole-dipole interactions. The local field, B_{loc} of any nucleus is influenced by the presence of neighboring dipoles. The effect on a given nucleus, I is described in Equation (8), where μ_s is the magnetic moment of a neighboring nucleus S, r_{IS} is the distance between nuclei I and S, and θ is the angle between the internuclear vector and the static B_0 field.

$$B_{\text{loc}} = \pm \mu_s r_{\text{IS}}^{-3} (3 \cos^2 \theta_{\text{IS}} - 1) \quad (8)$$

In solution, the rapid tumbling causes an averaging of the local field over all orientations that yields a net local field of zero. In the solid state, this averaging process does not occur, and the sum of all of the dipolar interactions yields linewidths on the order of kilohertz.

The other important contribution to broad overlapping lines in solid state NMR spectra is chemical shift anisotropy (CSA). As discussed earlier, the chemical shift is affected by electrons that shield the nucleus from the applied magnetic field. The magnitude of this shielding is a function of the particular orientation of the molecule in the magnetic field. Like the dipolar interactions, the effects of CSA averages out to zero in solution, but not in the solid state. The angular dependence of the CSA also takes the form $(3 \cos^2 \theta - 1)$

where θ is the angle between the B_0 field and the principle axis of the chemical shift (e.g., the C—O bond for a carbonyl carbon). The combined effects of dipolar coupling and CSA yield the tremendously broad lines observed in solid-state NMR.

Magic Angle Spinning and Cross-Polarization

The challenge of solid state NMR is to narrow the linewidths to an extent that the spectrum can be interpreted in a manner similar to a solution NMR spectrum. This challenge was met by noting that the $(3 \cos^2 \theta - 1)$ dependence of the dipolar interactions and CSA goes to zero when the angle θ is set to 54.7° , the magic angle. If a sample is spun about an axis oriented at the magic angle relative to B_0 , the average orientation of the crystal axes will be equal to the magic angle and the anisotropic effects will be greatly diminished. The very strong dipolar interactions between ^{13}C and the attached protons may still yield broadened lines, therefore ^1H decoupling is often used in addition to magic angle spinning to achieve narrow lines in ^{13}C spectra.

The most widely studied nucleus in solid state NMR of pharmaceuticals is ^{13}C . As in solution, observation of ^{13}C suffers from inherently low sensitivity. Additionally, ^{13}C nuclei in the solid state have very long relaxation times, which limits the number of scans that can be acquired in a given amount of time. To enhance the sensitivity and allow for faster repetition rate, cross-polarization (CP) methods have been developed. CP is very analogous to spin polarization transfer. A train of simultaneous rf pulses on both the ^1H and ^{13}C is used to transfer the ^1H magnetization to the ^{13}C . In this way, the intensity of the ^{13}C line is greatly increased and the pulse repetition rate is dependent upon the ^1H and not the ^{13}C relaxation. Cross-polarization magic angle spinning (CP-MAS) experiments constitute the majority of solid state NMR studies in the pharmaceutical industry and provide the foundation for many of the more advanced techniques.

Applications of Solid State NMR

Gel-phase NMR

The synthesis of combinatorial libraries relies heavily on solid phase synthetic methods. Previously the analysis of these libraries, using high throughput flow NMR methods was discussed. These analyses relied on the cleavage of the product from the solid phase support. In some cases, the cleavage reaction can be very harsh, and it is often desirable to analyze the solid phase reaction product with the compound still attached to the bead. Given the macromolecular

Fig. 13 a) ¹H spectrum of the “gel-phase” compound shown taken using a conventional 5-mm liquids probe. (100 mg sample suspended in 600 μ l DMSO-*d*₆, 500 MHz) b) ¹H spectrum of the same sample taken using the Varian Nano-probe (Varian NMR Instruments Palo Alto, CA, USA) probe with magic angle spinning (10-mg sample suspended in 30 μ l of DMSO-*d*₆, 500 MHz). (From Ref. 40.)

size of the bead, simply placing a sample of the solid phase material into an NMR tube would give spectra with broad overlapping lines. Magic angle spinning has been applied in order to narrow the lines of solid phase combinatorial samples (39). As the solid phase supports are swollen by solvents and therefore have properties that are neither distinctly solution phase nor solid phase, the term “gel-phase” NMR is used. This technique was used by Fitch and coworkers to generate 500 MHz spectra of organic

compounds bound to SPS resins with linewidths as narrow as 4 Hz (40). Fig. 13 shows the spectra of a “gel-phase” sample taken with conventional NMR methods and with magic angle spinning.

Polymorph studies

It has been estimated that approximately 30% of organic compounds crystallize in two or more forms that differ in the conformation and/or arrangement of molecules in the crystal lattice (41, 42). The crystalline form of a drug can have profound effects on the physicochemical properties. The density, melting point, dissolution rate, bioavailability, and ease of formulation are all influenced to some degree by the crystal form. Polymorphism is defined as the ability of a compound to exist in more than one solid-state form with identical chemical structures, but different crystal lattices. Solvates are an important form of polymorphism in which the crystal lattice changes by the inclusion of solvent. Given the influence of polymorphic forms on physicochemical properties, characterization of all polymorphic forms present in a drug substance is becoming a requirement of the relevant regulatory agencies.

Fig. 14 Solid-state ¹³C CP-MAS spectra of two polymorphic forms of lamivudine recorded at 125 MHz a) Form II, b) Form I. Signals indicated by asterisks are spinning sidebands. (From Ref. 43.)

Solid-state NMR has emerged as a powerful tool in the analysis of polymorphic drug forms. ^{13}C CP-MAS spectroscopy can be used to identify the number of crystallographically inequivalent sites in a unit cell and to understand the molecular structure on the basis of the chemical shifts. Fig. 14 shows the solid-state ^{13}C spectra of two forms of lamivudine (43). Form II shows a relatively simple spectrum in which there is only one molecule in the crystallographic asymmetric unit. The spectrum of Form I is much more complex, especially in the region from 80 to 100 ppm. Analysis of this spectrum indicates that there are five distinct molecules in the unit cell. This rare phenomenon was subsequently confirmed by X-ray diffraction.

Solid-state structural studies

Standard 1D ^{13}C CP-MAS spectra provide highly valuable data in terms of characterizing a single polymorph or determining the number of polymorphs in a sample, but high resolution structural data on solid materials requires more sophisticated methods. These methods include CP-MAS variants of some of the 2D methods described earlier that can yield through-bond and through-space connectivities (44) and typically require the use of selective or uniform isotopic labeling. A detailed study of the polymorphic forms of cimetidine was carried out using selective ^{13}C labeling. The distance constraints obtained in this study were used in molecular modeling studies to determine the possible conformations of cimetidine present in the different polymorphs (45).

FUTURE DIRECTIONS—SMALLER, FASTER, EASIER

The challenge of NMR in the pharmaceutical industry is to provide the intrinsically high information content of NMR spectra on smaller sample amounts, more rapidly, and with less time-intensive interpretation. Currently, each of these areas are the focus of intensive research efforts. Sensitivity gains can be expected with further innovations in probe design and with higher magnetic fields. Advances in experimental design will continue to provide more detailed information for both the qualitative and quantitative analyses of pharmaceutical compounds. The rapid analysis and interpretation of NMR data is being addressed with advances in computational methods (46). Improvements in spectral prediction and automated structure elucidation will greatly reduce the interpretation bottleneck in NMR applications. These advances, along with those yet

uncovered, will insure that NMR assumes an even greater role in essentially all aspects of pharmaceutical research and development in the future.

INTRODUCTION

In the 1800s, manufacturers used extravagant promotional techniques, which were reflective of the nation's level of culture and taste, to sell their products. Exaggerated statements regarding the products and its effects were very common. Professional standards and ethics were at an all-time low and virtually nonexistent in most cases. Patients, who had to make a choice between a myriad of medication products, were usually confused and ignorant of the medication use process. It was not surprising that most of these patients turned to home remedies for minor illnesses and self-care during such episodes. Today, the self-care movement has progressed forward by leaps and bounds with consumers having autonomy in making most of their health care decisions with the vast amount of information and products currently available to them.

Although the selection and number of products sold from country to country may vary, the group of drugs or medications sold throughout the world are easily distinguishable into two general categories, namely, those obtained with a doctor's prescription and those that can be obtained without one. The latter collection of products are normally classified as nonprescription drugs or over-the-counter (OTC) medications and are discussed in this article. Both nonprescription and OTC medications are used synonymously throughout this article.

SELF-CARE—SELF-MEDICATION

When consumers purchase and use nonprescription medications they are involved in a process that is popularly known as self-medication. Hence, nonprescription medications are products that are lawfully available for self-medication, without prior approval from a healthcare professional. Nonprescription medications are sold primarily for the prevention, treatment, and symptomatic relief of certain acute and chronic diseases. These products are not used for treating serious and complex conditions that necessitate the attention and direction of a licensed health practitioner. However, the main presump-

tion of providing nonprescription medications is the easy access available to consumers when the need arises.

Currently, nonprescription medications play a significant role in America's healthcare system by providing effortless access to more than 100,000 OTC drug products marketed using over 800 significant active ingredients. There are various categories of OTC medications available to consumers for treating minor symptoms of headache to problems of excessive acid secretion in the stomach. A list of symptoms or conditions treated with OTC products can be seen in Fig. 1. The top 20 selling nonprescription medications in the United States during the year 2001^[1] can be seen in Table 1. These top selling OTCs correlate with the medical ailments, which consumers report being most commonly self-treated (Table 2).^[2]

Nonprescription drugs are potent chemical entities and just like prescription drugs, should be viewed relative to their pharmacology, toxicology, contraindications, use, adverse effects, drug interaction potential, effectiveness, and special considerations in dosage and administration. It is significant to note that many nonprescription medications were, at one time, available as prescription drugs before being converted to OTC status. Therefore, it is important that the same precautions be taken when promoting and using nonprescription medications as their prescriptive counterparts.

SELF-CARE/SELF-MEDICATION MOVEMENT

The history of self-medication movement began in the late 1970s or early 1980s. Within this time period, there has been a huge movement towards self-help or self-care manifested by a positive approach to wellness and a determination to be involved in the decision making process regarding illness and its treatment. Availability of advanced technology such as computers and the Internet have allowed consumers to have access to a wealth of medical knowledge at their fingertips. Consumers in the 21st century are taking charge of their own personal health and evaluating the need for medical intervention.^[3] In addition, they are managing their symptoms and physical

Abrasions	Gastritis
Acne	Gingivitis
Aches and pains (general, mild to moderate)	Hair loss
Albumin testing	Halitosis
Allergic reaction	Head lice
Allergic rhinitis	Headache
Anemia	Heartburn
Arthralgia	Haemorrhoids
Asthma	Impetigo
Athlete's foot	Indigestion
Bacterial infection (topical, superficial, uncomplicated)	Ingrown toenails
Blisters	Insect bites and stings
Blood pressure monitoring	Insomnia
Boils	Jet lag
Bowel preparation (diagnostic)	Jock itch
Burns (minor, thermal)	Motion sickness
Calluses	Myalgia
Candidal vaginitis	Nausea
Canker sores	Nutrition (infant)
Carbuncles	Obesity
Chapped skin	Occult blood in feces (detection)
Cold sores	Ostomy care
Colds (viral upper respiratory infection)	Ovulation prediction
Congestion (chest, nasal)	Periodontal disease
Conjunctivitis	Pharyngitis
Constipation	Pinworm infestation
Contact lens care	Premenstrual syndrome Pregnancy (diagnostic)
Contraception	Prickly heat
Corns	Psoriasis
Cough	Ringworm
Cuts (superficial)	Seborrhea
Dandruff	Sinusitis
Deficiency disorders (mineral, vitamin, enteral food supplements)	Smoking cessation
Dental care	Sprains
Dermatitis (contact)	Strains
Diabetes mellitus (insulin, monitoring equipment, supplies)	Stye (hordeolum)
Diaper rash	Sunburn
Diarrhea	Teething
Dry skin	Thrush
Dysmenorrhea	Toothache
Dyspepsia	Vomiting
Feminine hygiene	Warts (common and plantar)
Fever	Xerostomia
Flatulence	Wound care

Fig. 1 List of selected medical disorders amenable to nonprescription drug therapy.

well-being independently, using diet, exercise, OTC medications, herbal supplements, or other forms of complementary care. These acts define the Self-Care movement, when the consumers act as an advocate for their own well-being using preventative medicine and algorithms of care.^[2] Self-care is what an individual does for himself to establish and maintain health and to prevent and deal with illnesses, whereas self-medication is the selection and use of medicines by individuals to treat self-recognized symptoms and illnesses. Self-medication is only a part of self-care, which is a broadly defined term.^[4] Numerous research studies, utilizing survey techniques, have shown a definite trend towards the use of self-care behaviors among

American consumers and that consumers are becoming increasingly comfortable with self-medication. According to a survey done by the Consumers Healthcare Products Association (CHPA), previously known as Nonprescription Drug Manufacturers Association (NDMA), 59% of respondents say they are more likely to treat their own health conditions today than they were in the past.^[5] Additionally, 77% of consumers would take an OTC medication when they are sick with a common everyday ailment. This is approximately twice as many as those who would consult a physician or take a prescription medication. This illustrates the fact that informed, appropriate, and responsible use of nonprescription drugs is an important

Nonprescription Drugs

Table 1 Top 25 most popular OTC drugs

Rank	Product name
1	Private label internal analgesic tablets
2	Tylenol internal analgesic tablets
3	Private label cold/allergy/sinus tablets/packets
4	Advil internal analgesic tablets
5	Nicorette antismoking gum
6	Aleve internal analgesic tablets
7	Private label first-aid ointments/antiseptics
8	Benadryl cold/allergy/sinus tablets/packets
9	Nicoderm CQ antismoking patch
10	Private label antacid tablets
11	Bayer internal analgesic tablets
12	Tylenol PM internal analgesic tablets
13	Private label cold/allergy/sinus liquid/powder
14	Pepcid AC antacid tablets
15	Private label laxative tablets
16	Halls cough/sore throat drop
17	Vicks Nyquil cold/allergy/sinus liquid/powder
18	Zantac 75 antacid tablets
19	Excedrin internal analgesic tablets
20	Motrin IB internal analgesic tablets

(From Ref. [1].)

part of the self-care process. Problems with self-medication may arise when the consumers take OTC medications along with other prescription drugs, which may lead to overdose of a drug. A study was done in which consumers were given a personal education program and it has been shown that this program proved to be more effective in changing the consumer's self-medication behavior.^[6] It has been suggested that OTC medication use is a common self-care behavior and therefore the patient's OTC medication use data should be collected while recording medication history.^[7,8]

Table 2 Consumer use of OTC medications by ailment

OTC category	Use (%)
Headaches	81
Cold/cough/flu/sore throat	72
Skin problems	68
Heartburn/indigestion	66
Allergy/sinus	58
Premenstrual	53
Constipation/diarrhea	49
Muscle/joint/back pain	49
Upset stomach/nausea	46
Minor eye problems	46
Teeth/gum problems	30
Menopausal symptoms	19

(From Ref. [2].)

Why Do Consumers Use OTCs?

Access to self-medication options empowers consumers and enhances their desire to take control of their own health conditions. Some important reasons why consumers use nonprescription medications include convenience, cost, time, and their attitudes, values, and beliefs.^[5] Consumers turn to nonprescription medications for 38% of all health problems they experience.^[9] It is known that consumers in the United States use more nonprescription medications than anywhere else in the world, with the sale of these products exceeding \$30 billion dollars annually.^[10] Sales of OTCs have increased steadily over the years. Table 3 provides a 5-yr trend analysis of OTC sales by category.^[11] Yet for this vast volume, OTC medications still take up less than 2 cents of every healthcare dollar spent by an individual.^[12,13] In addition to the clinical and economic benefits of using nonprescription products, 92% of consumers report they are satisfied with the medications they have used for self-care.^[14]

These benefits not only accrue to the individual, but to society as well. The resource savings to the healthcare system through responsible self-medication allows better allocation of limited healthcare resources and physicians' time to important issues beyond the scope of self-care. It is inconceivable to consider the tremendous economic strain it could impose on the healthcare system if every consumer chose to visit a physician for every minor illness. Health centers would be overwhelmed and would not be able to work efficiently as illustrated by the fact that on an average each American experiences one potential self-treatable health problem every 3–4 days.^[5] Additionally, approximately 90% of the Americans consider themselves in poor health at least one or more times each month.^[5] Approximately 70% of consumers self-medicate on a regular basis, and an estimated 40% of the U.S. population uses at least one nonprescription drug within any given 48-hr period.^[5] Hence, easy access to nonprescription products is likely to be a priority for the American consumer.

OTC AVAILABILITY AND ABUSE

Because of these prevailing sentiments, unlike in other countries, nonprescription medications are available virtually everywhere in the United States. Even vending machine laws have been implemented that sanction the use of mechanical devices and vending machines for the sale of nonprescription drugs. These products are also widely available on the Internet and may have been the cause of various abuse cases involving teenagers and OTC cough and cold products. Recent statistics from the American Association of Poison Control Centers 2001 report that

**Table 3** OTC sales trends by major category

OTC category	1996 (\$)	1997 (\$)	1998 (\$)	1999 (\$)	2000 (\$)

(From Ref. [11].)

the number of cases involving abuse or self-harm from nonprescription cough and cold products increased to 13,393 in 2000 from 9,889 in 1999.^[15] Combination products containing ingredients like dextromethorphan and chlorpheniramine are being used to experience the pleasures of drug abuse such as those experienced by LSD.^[14] Unfortunately, the danger of ingesting high amounts of these products can cause deleterious effects on the cardiac system and the central nervous system. Hallucinations, delirium, high body temperatures, and dizziness can occur when these ingredients are abused. Additionally, many of these products also contain acetaminophen (APAP) that can cause liver toxicity when used in high doses. Pharmacists employ several methods to limit patient access to products of abuse. The most common technique is to keep the product out of sight.^[16] Other techniques include additional client questioning, providing advice, and limiting the quantity of product sold.^[16] Pharmacists need to be aware of the

misuse of these products and counsel consumers on the proper use and dangers of taking excessive doses.

Unlike the United States, many countries further divide nonprescription medications into different subclasses. Table 8 contains information regarding OTC products around the world. For example, in the United Kingdom, nonprescription medications known as P medicines may only be sold in registered pharmacies under the supervision of a registered pharmacist while other nonprescription medications, known as the general sale list medicines, may be sold at all other retail outlets. There has been a push in recent years to consider a third class of medications sold only under the supervision of the pharmacist in the United States.^[17] Many consumers and healthcare providers favor this move with more and more products available as OTCs. However, limiting the access to these products, especially in rural areas, has kept this issue still under debate.

INFORMATION SOURCES

Patients are exposed to volumes of information concerning OTC medications through a variety of sources.^[3] These include but are not limited to package labels, advertisements, advice from healthcare professionals, books, magazines, journals, and family members. It is essential, however, to recognize the value and significance of the key information made available to consumers through the proper labeling of nonprescription medications. The package label is one of the most important sources of information for consumers because it provides information at the time of purchase and at the time of product use. To ensure the safe and effective use of nonprescription products by consumers, the U.S. Food and Drug Administration (FDA) has developed specific guidelines that must be adhered to by all commercial manufacturers.^[18] These guidelines will be elucidated in depth in the following discussion.

OVER-THE-COUNTER HUMAN DRUGS: LABELING REQUIREMENTS—THE FDA GUIDELINES

The movement to reform OTC medication labels started in 1990, when the pharmacist planning service of Sausalito, California, together with various citizen groups petitioned the FDA to set standards for print size and style on the label of nonprescription medications.^[19] The FDA subsequently published a notice summarizing the contents of the citizen's petition and their comments on labeling of OTC medications in the Federal Register. In 1991, the NDMA convened a task force that conducted a comprehensive literature review and identified four factors that could affect the readability of OTC medication labels.^[19] These include medical, comprehension, illumination, and technical aspects necessary to improve OTC medication labels. These factors were addressed in the NDMA Label Readability Guidelines and included a set of recommendations that the drug manufacturers could adopt voluntarily.^[19] The FDA further requested comments from the public on font sizes, types, color, and various label design techniques that could enhance readability after the NDMA recommended their guidelines.

The American Pharmaceutical Association (APhA) suggested focusing particularly on four categories of information within a standardized format, which include primary use, dosing, cautions and major side effects, and active ingredients.^[19] A study conducted by Sansgiry and colleagues convinced the FDA that new guidelines were required for OTC labeling.^[20] This study concluded that the font size on OTC medication labels was very small and

consumers had difficulty reading the labels.^[20] Finally, in March 1999, the FDA published the new guidelines, entitled "Over-the-Counter Human Drugs: Labeling Requirements," mandating certain information on OTC drug labels.^[18]

The new label format should convey essential information to the consumer in a user-friendly format and provide consumers with improved information about the most suitable OTC medication for their condition, understanding its benefits and risks. The FDA has given 6-yr time for all the products to adopt the new labeling format with the first implementation of the rules to occur for most drugs during 2002.^[21] The time of labeling change is dependent on the date of the final monograph for each individual product. A drug that lacks the new label after its required implementation time will be considered misbranded and subjected to all the enforcement by the FDA. This labeling format would include a standardized drug facts panel, which includes information on active ingredients, purpose, use, and warnings.^[22] An example of a label with the new format can be seen in Fig. 2. Other proposed improvements include easier to read 6-point Helvetica type, distinct sections presented in standard order, and adequate spacing between letters, words, and lines of text. Fig. 3 includes an explanation on certain aspects of the new OTC labeling guidelines that were recommended.^[23]

SELECTING OTC MEDICATIONS

When it comes to selecting a nonprescription medication, it is important for the consumer to also understand the limitations and dangers of these drugs. Individuals must be educated that medications purchased OTC should never be taken for longer time periods or in higher doses than the label recommends. Symptoms that persist are a clear signal that it is time for triage to their physicians. It is also important to point out to consumers that they must read the label completely each time they purchase a product. Many times, two products from the same brand family are neither meant to treat the same condition nor may they contain the same active ingredient. This issue is further discussed in the section "OTC Brand Name Confusion."

The FDA felt the best way for consumers to select any OTC product is to cautiously read the label and talk to the pharmacist or physician in case of questions or doubts before product use. There are several things that the consumer should look for, when selecting an OTC medication, specifically the warnings. The important sections of the label that consumers need to review and evaluate before making purchase decisions can be seen in Table 4.

Drug Facts							
Active ingredient (in each tablet)	Purpose						
Chlorpheniramine maleate 2 mg	Antihistamine						
Uses temporarily relieves these symptoms due to hay fever or other upper respiratory allergies: ■ sneezing ■ runny nose ■ itchy, watery eyes ■ itchy throat							
Warnings Ask a doctor before use if you have ■ glaucoma ■ a breathing problem such as emphysema or chronic bronchitis ■ trouble urinating due to an enlarged prostate gland Ask a doctor or pharmacist before use if you are taking tranquilizers or sedatives							
When using this product ■ you may get drowsy ■ avoid alcoholic drinks ■ alcohol, sedatives, and tranquilizers may increase drowsiness ■ be careful when driving a motor vehicle or operating machinery ■ excitability may occur, especially in children If pregnant or breast-feeding, ask a health professional before use. Keep out of reach of children. In case of overdose, get medical help or contact a Poison Control Center right away.							
Directions <table border="1"> <tbody> <tr> <td>adults and children 12 years and over</td> <td>take 2 tablets every 4 to 6 hours; not more than 12 tablets in 24 hours</td> </tr> <tr> <td>children 6 years to under 12 years</td> <td>take 1 tablet every 4 to 6 hours; not more than 6 tablets in 24 hours</td> </tr> <tr> <td>children under 6 years</td> <td>ask a doctor</td> </tr> </tbody> </table>		adults and children 12 years and over	take 2 tablets every 4 to 6 hours; not more than 12 tablets in 24 hours	children 6 years to under 12 years	take 1 tablet every 4 to 6 hours; not more than 6 tablets in 24 hours	children under 6 years	ask a doctor
adults and children 12 years and over	take 2 tablets every 4 to 6 hours; not more than 12 tablets in 24 hours						
children 6 years to under 12 years	take 1 tablet every 4 to 6 hours; not more than 6 tablets in 24 hours						
children under 6 years	ask a doctor						
Other information store at 20-25° C (68-77° F) ■ protect from excessive moisture							
Inactive ingredients D&C yellow no. 10, lactose, magnesium stearate, microcrystalline cellulose, pregelatinized starch							

Fig. 2 Example of proposed OTC drug label format. (From Refs. [18], [23].)

Other ways to increase consumers' ability to read labels is to make sure that there is enough ambient light available at the point of display. It usually takes three times more light to read the same line at age 60 than at age 30.^[19] Elderly and the vision impaired should be advised to wear glasses or use magnifying glasses while reading labels to improve visibility.

U.S. FDA OTC REVIEW AND REGULATIONS

In the following, the acronym FDA will be used synonymously for U.S. FDA. The first legislation concerning the regulation of drugs in the United States was the Pure Food and Drug Act of 1906. This major federal law required that drugs only meet the standards of

Factor	Recommendation by FDA
Clear, easy to read type style	Helvetica or universe with no more than 39 characters per inch.
Bullets	Solid square or circle, 5 point type.
Text	Left justified
Hyphenation	Absent
Uppercase and lowercase letters only	No all caps
Font size	6 points (dark on light)

Fig. 3 New FDA guidelines for OTC medication labels. (From Refs. [18], [21], [22].)

**Table 4** Sections on OTC labels that consumers should consider before purchase

No.	Item	Comments
1	Product name	Is this the product that was recommended?
2	Active ingredients	Therapeutic substances in medicine
3	Purpose	Product category (such as antihistamine, antacid, or cough suppressant)
4	Uses	Symptoms or diseases that the product will treat or prevent
5	Warnings	When not to use the product, when to stop taking it, when to see a doctor, and possible side effects
6	Directions	How much to take, how to take, and how long to take it
7	Other information	Such as storage information
8	Inactive ingredients	Substances such as binders, colors, or flavoring agents. Some consumers may have allergies to these ingredients
9	Expiration date	Make sure the product has not expired or will expire during normal length of use
10	Tamper/child resistant packaging	Make sure all tamper resistant packaging is intact or do not purchase the product. Each product is allowed to have one dosage unit available that does not contain a child safe container in order to allow the elderly or infirmed patient to have the ease and accessibility to their medication

strength and purity claimed by the manufacturers. Drug safety was not mandated by law until the passage of the Federal Food, Drug, and Cosmetic (FDC) Act of 1938, which was prompted by negative reports on sulfanilamide. This act made no clear distinction between prescription and OTC medications but stated that all drugs must be safe for their intended use. No mention was made concerning the effectiveness of drugs in this legislation but labeling provisions were mandated which stated that products must be labeled with “adequate directions for use with conspicuousness and in terms such as to render it likely to be read and understood by the ordinary individual under customary conditions of purchase and use.”^[24] The 1951 Durham-Humphrey Amendment set up specific standards for classification that distinguished between a prescription and OTC medication. The prescription drug category included those medications that were deemed habit forming or toxic. Those medications were used for conditions that could not be self-diagnosed, and medications needing skills to administer or use them beyond the scope of the normal consumer were also included. This legislation eliminated consumer oriented labeling requirements for prescription products as these products could now be obtained only through prescriptive authority of a physician.

In 1962, the Kefauver-Harris amendments to the Food, Drug, and Cosmetic Act were passed, requiring that drug products be proved not only safe but also effective for their intended uses. Drugs on the market before 1938 were

grandfathered, but the 4500 new drug products, including 512 nonprescription products marketed after 1938, were to be reviewed by the FDA and removed from the marketplace if not found efficacious. The FDA, after contracting with the National Academy of Sciences/National Research Council (NAS/NRC) in 1966, began a procedure called Drug Efficacy Study Implementation (DESI) to assess the effectiveness of these products. It quickly became evident that there was a need to implement an extensive examination of the nonprescription medications in the marketplace. In 1972, the FDA began a large-scale scientific review of the more than 700 active ingredients in 300,000 different formulations to ensure that they were safe, effective, and properly labeled.^[24] This process commonly known as the “OTC Drug Review” was responsible for reclassifying many drugs from prescription to nonprescription status and for establishing regulations for proper labeling. It was made up of 17 expert panels that convened over a 10-yr period. Manufacturers submitted scientific literature to the group showing the effectiveness of their products. These expert panels developed monographs for each ingredient, developed antacid testing procedures, removed daytime sedatives from the market, created the SPF rating scale, implemented procedures for tamper resistant packaging, developed a tooth paste abrasion index, and put into action the aspirin-Reye’s syndrome warnings on aspirin containing products.

DRUG APPROVAL PROCESS

The 1938 FDC act required that all new drugs, including new drug products introduced after 1938, be proven safe for human use before being marketed and be cleared in advance through a new drug application (NDA). However, FDA's OTC drug review evaluated all nonprescription drugs for safety, effectiveness, and labeling, regardless of the date of marketing entry. The 1938 FDC act defines the market being divided into new drugs, which are defined by law as being recognized as safe and effective (RASE), and those that are generally recognized as safe and effective (GRASE). During phase I of the process, an Advisory Review Panel was set up, which gave advanced notice of proposed rulemaking. At this time a drug was given one of three different categories:

- Category I—GRASE.
- Category II—not recognized as safe and effective (NRASE).
- Category III—insufficient evidence to prove safety and efficacy.

Phase II deliberations then began, the outcomes of which concluded if the product can continue to be marketed pending further review or if the manufacturers need to reformulate their product in order to include it in Category I. During this phase, manufacturers were given a tentative final monograph that was printed in the Federal Register. The Final Rule, phase III, was also published in the Federal Register and explained if the product was safe and effective (Category I) and met monograph conditions or if the product was classified as not having met monograph conditions (Category II and III). This gave manufacturers the time necessary to prove their drugs safe and effective before marketing.

NEW DRUG APPLICATION PROCESS

One mechanism of gaining general recognition status for nonprescription drugs approved by the FDA's OTC review was through an NDA. NDA is necessary for a drug that is defined by law as NRASE until it has been precleared and approved by the FDA. Because of the OTC drug review, excess of 40 primary products have been reclassified from prescription to OTC. There are three ways in which such a change can be made outside the drug review process.^[24] The manufacturer may file an NDA if the clinical research data, which proves that the drug can be approved for an OTC indication or OTC dosage levels, is available. The FDA itself can file for reclassification if it is determined that prescription status is not necessary for the safe and effective use of the drug.

If the postmarketing safety experience of a drug can prove that the drug can be used safely without physician supervision, then a supplement to the NDA can be filed. For the drug to be even considered for the OTC status, the drug should meet certain criteria^[25]:

1. The indication or indications that the product is to be used as an OTC drug should be similar to the prescription indication or indications, and it must allow for easy self-diagnosis and monitoring by the patient.
2. The drug to be considered should not have unfavorable adverse event(s) and drug interaction(s). The drug should have relatively low toxicity and low potential for abuse.
3. The drug should not have a narrow therapeutic index nor require special monitoring or laboratory procedures to ascertain toxicity or therapeutic effect.
4. The drug should not have any other criteria that would make it impractical for OTC use.

Rx-TO-OTC SWITCH

In recent years, there has been a huge impetus for many drugs that were recognized as prescription only to be marketed as OTC medications. The reasons for this include patent expiration, increasing market share, and consumer demand. However, chronic conditions are a big hurdle for Rx-to-OTC switches and most of the drugs being switched are used for treating acute conditions (e.g., headache).^[26] This is because chronic OTC medication use raises questions about self-monitoring. Switches from prescription to nonprescription status have a huge impact on the health care economy. A list of some recently switched OTC medications can be viewed in Table 5. Studies have shown that these switched products can save Americans billions of dollars when taking into account prescription costs, doctor visits, insurance costs, and lost time from work.^[27] The overall effect of the Rx-to-OTC switch on healthcare costs is more than one can expect.^[28] The Wall Street Journal recently estimated that 30%–50% of healthcare costs for people over the age of 65 are for prescription drugs. A 1997 study showed that the American consumer could save approximately \$13 billion per year by using OTC medications switched from medications that had been available by prescription only.^[27] Additional information has suggested that a woman can save over \$80 by using switched OTC vaginal antifungal products for previously diagnosed recurring yeast infections.^[27] Furthermore, it has been recognized that consumers may save more than \$750 per year from cough/cold switches illustrated by the fact that doctor visits for the common cold fell by 110,000 per year

**Table 5** Examples of recent Rx-to-OTC switches

Product name	Manufacturer/distributor	Indication
Actron (ketoprofen)	Bayer Corp. Consumer Care	Internal analgesic
Axid AR (nizatidine)	Whitehall-Robins Healthcare	Stomach acid reducer
Lamisil AT (terbinafine hydrochloride 1%)	Novartis	Antifungal
Lotrimin Ultra (butenafine hydrochloride 1.0%)	Schering-Plough	Athlete's foot, jock itch, ringworm
Monistat 3 (miconazole nitrate 4.0%)	Advanced Care Products	Anticandidal
Orudis KT (ketoprofen)	Whitehall-Robins Healthcare	Internal analgesic
Pepcid AC (famotidine)	Johnson & Johnson-Merck	Stomach acid reducer
Rogaine (minoxidil 5.0%)	Pharmacia-Upjohn	Hair growth
Tagament HB (cimetidine)	SmithKline Beecham	Stomach acid reducer
Vagistat-1 (triconazole 6.5%)	Bristol-Myers	Anticandidal
Zantac 75 (ranitidine HCl)	Warner Wellcome	Stomach acid reducer

between 1976 and 1994, which resulted from switched products from prescription to OTC status.^[29] Rx-to-OTC switches account for over 30% of the total U.S. OTC market.^[27]

Types of Prescription to OTC Switches

There are two types of prescription to OTC switches: Complete Switch and Partial Switch. When a product becomes a nonprescription product with all dosage strengths, if more than one, switched with no prescription version of the product remaining, it is called a complete switch. An example of this type of switch is the changing of Nicorette gum from prescription to nonprescription status. Nicorette gum, 2 mg and 4 mg, is used OTC for smoking cessation. If a product has one or more doses that were formerly prescription only or the company manufactures lower strengths of the product that were previously unavailable on prescription but the higher doses still remain available only through prescriptions, then this is called a partial switch. An example of this switch is the Naproxen sodium preparations. Aleve, the OTC switched product, contains 220 mg Naproxen sodium per tablet, while Anaprox, 275 mg Naproxen sodium, is still available only by prescription. Benefits for a drug to be reclassified from prescription only to nonprescription status are numerous. The section "Benefits of Reclassification to OTC Status" will discuss benefits of Rx-to-OTC switches from manufacturers, consumers, and healthcare providers' prospective.

BENEFITS OF RECLASSIFICATION TO OTC STATUS

The potential for a product to be marketed for a longer period of time is quite an advantage for the manufacturer of a drug. By switching a drug that is threatened by patent

expiration from Rx-to-OTC status, it expands the market potential of the product and allows manufacturers to recoup the costs of bringing the drug to market originally. The switch from Rx-to-OTC also allows manufacturers to move into different competitive markets. The sale of an OTC switched product that was formerly prescription only has at times almost doubled or tripled.^[30,31] Because consumers tend to purchase more recognizable brand names when buying an OTC product, former prescription only products tend to capture a large market share when converted to OTC status. Approximately 50% of the drugs that were switched to OTC from prescription status are the top sellers in the U.S. marketplace.^[29]

Patients also benefit tremendously from the Rx-to-OTC switches. When a product that was formerly in prescription only status is classified as OTC, it allows patients to self-treat and gain more control over their health.^[31] This is especially true in cases where medical advice was once required, e.g., smoking cessation. The patient can now save time and money that was previously spent on visiting a physician. It has been shown that patients saved approximately \$150 million a year since hydrocortisone 1% was switched to OTC status.^[32]

The role of the pharmacist as a self-care advisor has been accentuated as more drugs are switched from Rx-to-OTC status and patients seek advice from accessible sources. Although manufacturers publish booklets on the use of their OTC products, counseling by the pharmacist is imperative. The pharmacist is the drug therapy expert and is in the best position to know what questions to expect from their patients and answer those queries as it pertains to their patient's individual health. As more and more OTC medications become available, the pharmacist will be consulted more often on drug interactions along with adverse effects and limitations of drug use for self-care. Finally, the pharmacist can advise the patient if they should be treating their condition with an OTC product or

seeking the advice of their physician. The topic regarding the role of pharmacist in self-care is discussed further in this article.

PROBLEMS WITH RECLASSIFICATION

A large issue of concern to the consumer is the cost of their medication. One issue with an Rx-to-OTC switch is that the drug, previously covered by an insurance company due to its prescription standing, is now no longer covered because of its change to OTC status. This may lead to patient confusion and frustration. Other factors that may contribute to these feelings include dual Rx and OTC marketing; in most of these cases, the OTC product is marketed in lower dose strength. However, in some cases the marketed OTC strength can be used to treat the same medical condition as the prescription strength of the product. Usually, the OTC strength should be used for a shorter duration of time or fewer times a day than the prescription strength, however this may lead to patient confusion over which dose of the medication is best to treat their particular symptoms. The second problem deals with the misperception regarding drug safety. Most patients feel that OTC medications are safe and totally free from side effects due to the OTC status. This perception may be due to the fact that consumers are allowed to buy OTC products without any consultation with a healthcare provider. This may lead consumers to make false assumptions about the safety and tolerability of a particular drug product, especially as it concerns other medications or health conditions they may have. Few consumers recognize that some OTC medications may have deleterious effects on their body including effects on blood pressure, blood glucose, and heart rate. A third problem concerns misleading advertisements by manufacturers. The limited medical knowledge of the patient makes them highly susceptible to such advertisements. These commercial advertisements help sway consumers to buy a particular product and can increase market share in the highly competitive OTC industry. Finally, an important concern of the healthcare practitioner concerning the reclassification is the loss of direct patient counseling over the medication. The FDA has recently attempted to rectify this by adding to the label of nonprescription medications the mandate to "ask your doctor or pharmacist before using this or any medications."^[18] With the advent of managed care and formulary management, insurance companies are also very interested in the Rx-to-OTC switch process. The petition brought forth to the FDA by WellPoint Health Networks, Inc. in 2001 exemplifies this change in attitude. This landmark case began as a campaign by California Blue Cross pharmacists. Blue Cross of California's parent

company, WellPoint Health Networks, Inc. petitioned the FDA to make three prescription antihistamines OTC: Claritin, Zyrtec, and Allegra. Schering-Plough, Pfizer, and Aventis, manufacturers of these products, opposed this change, claiming these drugs need to be monitored by doctors for safety reasons. Usually the manufacturer seeks the Rx-to-OTC change due to patent expiration, but in this case, the manufacturers were allied in the fact that these products were not ready to go OTC. Only once, in the last 18 yr, has the FDA approved nonprescription sales of a drug without a petition or support from the manufacturer. On May 11, 2001, the U.S. FDA advisory committee ruled that Claritin, Zyrtec, and Allegra should be sold OTC as allergy relievers. The advisory panel stated that manufacturers' own advertisements claimed that side effects of these drugs were no worse than placebo. The FDA said it agreed with that advice but issued no ruling. Surprisingly, seeing the potential for increased sales in the future, Schering-Plough Corporation decided to change tactics and filed an FDA application to switch Claritin voluntarily to nonprescription status, not only for nasal allergies but also for hives. The FDA went back to its advisors to ask if patients could correctly self-diagnose ordinary hives instead of a more serious rash, and if so, whether Claritin constituted an appropriate nonprescription treatment for this condition. Advisors to the FDA voted that enough evidence exists that Claritin can treat chronic hives without a sufferer needing a prescription but urged more studies for acute hives. The FDA is not bound by its advisers' recommendations but typically in the past has followed the advice of its advisory committees. It is evident that in the future we will see Claritin and many more products being marketed OTC.

OTC BRAND NAME CONFUSION

One major problem for the consumer brought about by the Rx-to-OTC switch process and the fact that manufacturers understand the draw of brand name recognition is that there is a great deal of confusion concerning ingredients used in a named drug product.^[33,34] Manufacturers retain the familiar trade names even though there are changes in the formula, because of immense brand loyalty. Pharmaceutical manufacturers spend a large percentage of their revenue on advertising their products to the general public through brand name recognition. A popular marketing tactic has been to use these established brand names to increase sales of other products in their line. This practice is known as creating line extensions. This sales tactic can be confusing to consumers especially if the product name carries over into entirely new and different product lines.^[33,34] For example, Tylenol[®], a product manufactured by McNeil could refer to analgesic, a cold

Nonprescription Drugs

11

medication, influenza medication, or a sinus product. The number of products with the Tylenol brand name marketed in the United States during 2000 can be viewed in Table 6. In other cases, a certain therapeutic outcome may be associated with a product's brand name that is not entirely accurate. The brand name product Fungi-nail[®], a solution manufactured by Kramer laboratories, implies that it will cure nail fungus. Although the pharmacist understands it is very difficult to achieve effective treatment of the nail fungus through topical treatment alone, consumers may not be aware. Brand loyalty is so important that manufactures often maintain a familiar trade name even though products in the line do not contain the same active ingredients. This is exemplified by Unisom sleep products: Unisom Sleep Gels[®] contain diphenhydramine hydrochloride as the active ingredient and Unisom SleepTabs[®] contain Doxylamine succinate as the sleep-causing agent. The pharmacist needs to be aware of and knowledgeable about these situations so they can counsel patients appropriately concerning patients' misconceptions.

THIRD CLASS OF DRUGS

Because of the confusion associated with OTC products and due to the numerous Rx-to-OTC switches, there are

many advocates of having a third class of drugs. Historically, the distribution of medicine in the United States is based on a two-class system: prescription and nonprescription. A nonprescription drug is one that the U.S. FDA has found to be safe and effective for direct consumer use based on the label instructions and warnings. A wider margin of safety is required for nonprescription drugs due to absence of physician and sometimes even pharmacist supervision. A third class of drugs would be available only through a pharmacist. Drugs in the third class would not be available in other convenient retail outlets, such as discount stores, grocery stores without a pharmacy, hotel gift shops, and convenience stores. The current two-class system serves two of the most fundamental demands of access and affordability. The FDA has repeatedly rejected a third class or transition class of drugs. As recently as March 9, 1994, the FDA stated that it would be inappropriate to restrict the sale of OTC drugs to pharmacies because such a restriction would reduce the number of outlets (from 750,000 to 65,000 nationwide) where consumers could purchase OTCs, limit competition, and raise some OTC drug prices, with no attendant public health benefit. Diminished competition will also have a disproportionate impact on traditionally underserved populations in urban and rural areas of the country. The U.S. Justice Department and the National Association of Attorneys General have opposed a third class of drugs, calling such proposals anticompetitive and anticonsumer because they create a monopoly in the distribution of nonprescription drugs.

Although the outlook for a third class of drugs is not bright, there are some groups that are proponents of this measure. The National Association of Boards of Pharmacy (NABP) passed a resolution in 1995 asking for legislation on this issue.^[35] The National Community Pharmacists Association (NCPA) passed a resolution in 1982 calling for a "pharmacist legend class" that would create a "buffer" period during which pharmacists could learn about and dispense newly switched medications before they are sold in locations with no healthcare intervention.^[35,36] The APhA also issued support for a third class of drugs.^[37] Finally, pharmacists themselves, understanding the ramifications of misuse of OTCs, backed the concept of a third class of medications that would only be available behind the counter.^[36] Unfortunately, this may be seen by opponents only as a special interest group trying to gain a monopoly on certain products to increase their own profits at the expense of other retailers. However, when more products are switched to OTC, consumer may find it confusing to remember all the information when making product choices, especially drug interactions. Hence, the issue of third class of drug may not be resolved yet.

Table 6 Example of potential confusion due to product line extensions

Brand name	Ingredients/dose
Tylenol	APAP 1000 mg
Tylenol PM	APAP 1000 mg Dextromethorphan hydrobromide 50 mg
Tylenol Cough	APAP 1000 mg Dextromethorphan hydrobromide 30 mg
Tylenol Sinus	APAP 1000 mg Pseudoephedrine hydrochloride 60 mg
Tylenol Allergy	APAP 1000 mg
Sinus	Pseudoephedrine hydrochloride 60 mg Chlorpheniramine maleate 4 mg
Tylenol Cold	APAP 650 mg Pseudoephedrine hydrochloride 60 mg Dextromethorphan hydrobromide 30 mg
Tylenol	APAP 650 mg
Multi-Symptom	Pseudoephedrine hydrochloride 60 mg Dextromethorphan hydrobromide 30 mg Chlorpheniramine maleate 4 mg

NONPRESCRIPTION DRUG ADVERTISEMENTS

Pharmaceutical companies spent an estimated \$1.8 billion on direct-to-consumer advertisements for prescription drugs in 1999.^[38] Although the FDA has the power to prohibit the sales of falsely advertised products, the FDA does not regulate or have authority over nonprescription drug advertising. Such an authority rests with the Federal Trade Commission (FTC). Consumers make product purchase decisions from the information that they receive through advertisements. If these advertisements are misleading, the consumers' drug knowledge is not adequate to detect this misinformation.^[39] This may lead to inappropriate purchases and possible adverse reactions. The Federal Trade Commission Act was amended in 1970 prohibiting the advertisers in using language that was not approved by the FDA, when describing the therapeutic benefit of nonprescription products. The standards imposed on prescription medications are more stringent than those for OTC medications. An advertisement for prescription medications not only points out the beneficial effects of the medication but also states contraindications and warnings. Advertisements for OTCs generally present only information on the beneficial effects of the medication, seldom mentioning contraindications or safety information. The FDA requires advertising to maintain a "fair balance," speaking to safety as well as efficacy. The FTC has no such requirement.^[40]

The National Association of broadcasters and the NDMA developed a code, which laid down the guidelines for manufacturers to follow in creating television advertisements for nonprescription drugs. According to these guidelines, the manufacturer among other things should also make sure that advertisements contain no claims of product effectiveness that are not supported by clinical or other scientific evidence and present no information suggesting that the product prevents or cures a serious condition that must be treated by a licensed practitioner.^[5] An in-depth discussion of OTC advertisements can be found in upcoming articles of the encyclopedia.

CONSIDERATION FOR SPECIAL AT-RISK POPULATIONS

Many segments of the population in the United States are considered high risk for any drug therapy because of differences in their ability to deal with side effects of medications, differences in their pharmacokinetic parameters as pertains to adsorption, distribution, and metabolism of drugs, or they have drug effects that are unique to their population due to age. These groups of

individuals may experience higher incidence of drug related problems than the typical patient. This is especially true in the nonprescription arena where these products are so accessible. Considering these issues the FDA had indicated a list of drug-drug interactions (Table 7).^[41] Products for pediatric individuals, pregnant or lactating women, and the geriatric consumers require special attention and monitoring when it comes to OTC medications.

While many OTC drugs can be used during pregnancy and lactation under a physician's supervision, some are known to be unsafe. As indicated on product labels, women who are pregnant, who may be pregnant, or who are nursing should consult a doctor before taking OTC medication.^[42,43] Women, who are pregnant or lactating, should be discouraged from using nonprescription medications without consulting their primary care provider. It is important to know what trimester a woman is in during her pregnancy because certain OTC medications can be used safely during different times of gestation. During breast-feeding, many medications can pass into the breast milk causing problems to the nursing infant. Nursing mothers who need to take OTC medications should take them right after breast-feeding or before an infant's nap period.^[43] Additionally, breast-feeding women should avoid products that are advertised as extra-strength, maximum strength, or long acting. Pregnant and lactating women should be advised to use nonpharmacological modalities whenever reasonably possible.

Children under 2 yr should not be given any OTC drug without doctor's approval. Before parents administer OTC drugs to their young children, they should consider whether they are truly necessary for the child.^[44] One of the major problems associated with recommending OTC medications to children is that it is difficult to extract an accurate medical history from them. Although most of the time a second hand history is available through their parents, it is difficult to recommend a nonprescription medication that will truly meet their needs for symptomatic relief. Additionally, most nonprescription medications do not include dosing information for those youngsters under the age of 2 yr, even those medications packaged for children. Several studies have indicated the inappropriateness of administering OTC cough and cold medications to a pediatric population.^[45-49] These OTC cough and cold medications are associated with several serious side effects in children.^[50-62]

Another potential population at risk that also consumes the most number of OTC products are the elderly. Nonprescription medications should be administered to the geriatric individual only after a complete assessment of comorbid disease states. Social, economic, and physiological factors all weigh into the decision of what OTC

**Table 7** Selected OTC drug interaction warnings for some OTC drug products

Product category	Drug interaction information
Acid reducers H2 receptor antagonists	For products containing cimetidine, ask a doctor or pharmacist before use if you are: taking theophylline (oral asthma drug), warfarin (blood thinning drug), or phenytoin (seizure drug)
Antacids	Ask a doctor or pharmacist before use if you are: allergic to milk or milk products if the product contains more than 5 g of lactose in a maximum daily dose taking a prescription drug Ask a doctor before use if you have: kidney disease
Antiemetics	Ask a doctor or pharmacist before use if you are: taking sedatives or tranquilizers Ask a doctor before use if you have: a breathing problem, such as emphysema or chronic bronchitis glaucoma or difficulty in urination due to an enlarged prostate gland When using this product: avoid alcoholic beverages
Antihistamines	Ask a doctor or pharmacist before use if you are taking: sedatives or tranquilizers a prescription drug for high blood pressure or depression Ask a doctor before use if you have: glaucoma or difficulty in urination due to an enlarged prostate gland breathing problems such as emphysema, chronic bronchitis, or asthma When using this product: alcohol, sedatives, and tranquilizers may increase drowsiness avoid alcoholic beverages
Antitussive	Ask a doctor or pharmacist before use if you are: taking sedatives or tranquilizers Ask a doctor before use if you have: glaucoma or difficulty in urination due to an enlarged prostate gland
Bronchodilators	Ask a doctor before use if you: have heart disease, high blood pressure, thyroid disease, diabetes, or difficulty in urination due to an enlarged prostate gland have ever been hospitalized for asthma or are taking a prescription drug for asthma
Laxatives	Ask a doctor before use if you have: kidney disease and the laxative contains phosphates, potassium, or magnesium stomach pain, nausea, or vomiting
Nasal decongestants	Ask a doctor before use if you: have heart disease, high blood pressure, thyroid disease, diabetes, or difficulty in urination due to an enlarged prostate gland
Nicotine replacement products	Ask a doctor before use if you: have high blood pressure not controlled by medication have heart disease or have had a recent heart attack or irregular heartbeat, since nicotine can increase your heart rate Ask a doctor or pharmacist before use if you are: taking a prescription drug for depression or asthma using a prescription nonnicotine stop smoking drug Do not use: if you continue to smoke, chew tobacco, use snuff, or use other nicotine-containing products
Nighttime sleep aids	Ask a doctor or pharmacist before use if you are: taking sedatives or tranquilizers

(Continued)

**Table 7** Selected OTC drug interaction warnings for some OTC drug products (*Continued*)

Product category	Drug interaction information
	Ask a doctor before use if you have: a breathing problem such as emphysema or chronic bronchitis glaucoma difficulty in urination due to an enlarged prostate gland When using this product: avoid alcoholic beverages
Pain relievers	Ask a doctor before taking if you: consume three or more alcohol-containing drinks per day
Stimulants	When using this product: limit the use of foods, beverages, and other drugs that have caffeine. Too much caffeine can cause nervousness, irritability, sleeplessness, and occasional rapid heartbeat be aware that the recommended dose of this product contains about as much caffeine as a cup of coffee
Topical acne	When using this product: increased dryness or irritation of the skin may occur immediately following use of this product or if you are using other topical acne drugs at the same time. If this occurs, only one drug should be used unless directed by your doctor

(From Ref. [41].)

medications should be suggested for the elderly individuals. Pre-existing medical conditions may affect the choice and use of nonprescription medications. For example, the use of nonprescription antihistamines should be avoided for those with glaucoma, urinary retention from benign prostatic hypertrophy, and emphysema. Many of the OTC sympathomimetics seen in the decongestants contained in nonprescription cough and cold medications may have effects on blood pressure and blood glucose in those patients with hypertension or diabetes, respectively. The elderly population consumes more drugs than any other group in our society. Because of this, polypharmacy, or the use of multiple medications plays a role in the use and choice of nonprescription medications. Many elders suffer from osteoarthritis or other diseases of pain and inflammation. Prescription and OTC medications may both contain ingredients that treat their pain but may contribute to stomach bleeding as a side effect of some pain medications. It is important for the geriatric individual to understand all the medications he is taking and the names of the active ingredients so they do not duplicate therapy. This group of patients is also prone to higher drug–drug interactions due to the high possibility of concurrent therapy. Pharmacokinetics parameters in the form of decreased renal function or liver function may also play a role in the elimination and possible toxicity of certain nonprescription medications. In summary, the special needs and risks of these groups of people need to be taken into account when recommending nonprescription drugs.

OTHER POTENTIAL DRUG THERAPY RISKS

There is a general misconception that since OTC medications are readily available, they are safe to be used by adults.^[63] It has been stressed throughout this article that because OTC medicines are available without a prescription does not mean that they should be taken without careful thought and consideration. When used by the wrong person, in the wrong dose, or in the wrong combinations, they can actually endanger the life they are meant to improve. An example of this is that Aspirin contributed to 33 intentional and accidental deaths in 1998, the most recent year for which data is available from the American Association of Poison Control Centers.^[64] APAP has recently come under attack for problems with liver toxicity. APAP is the most widely used pharmaceutical analgesic and antipyretic agent in the United States and the world; it is contained in more than 100 products. As such, APAP is one of the most common pharmaceuticals associated with both intentional and accidental poisoning.^[64] It is available OTC in 325 mg and 500 mg dosage forms. It is also found as a component of many prescription pain relievers including Darvocet, Percocet, and others. The maximum daily dose of APAP is 4 g in adults and 90 mg kg⁻¹ in children. The toxic dose of APAP after a single acute ingestion is 150 mg kg⁻¹ or approximately 7 g in adults, although the at-risk dose may be lower in persons with alcoholism and other susceptible individuals. However, when dosing recommendations are followed, the risk of liver toxicity is extremely small.^[64]

It is important that consumers understand the maximum dosages for OTC medications and read the labels to understand how often and how long they should self-treat their medical conditions so they do not overdose on these drugs. Overdose is an obvious pitfall to avoid, but even the right dose in combination with the wrong underlying condition can cause problems. The age of information technology has provided a lot of convenience to patients who have an access to the World Wide Web. There are several web sites available on the Internet (www.med-broadcast.com, with the Drug Check option) that actually allow users to enter the name of the drug, brand, or generic and provide all kinds of information ranging from how the medication works to contraindications. These sites would definitely help in decreasing the risk of wrong medications and would help the patient to know in advance the types of side effects they should expect. A list of websites that deal with the self-care industry around the world can be viewed in Table 8.

ROLE OF PHARMACIST IN NONPRESCRIPTION PRODUCT THERAPEUTICS

As one of the most trusted professions, the pharmacist exercises a lot of influence on the choice of OTC medication by patients. Research shows that 52% of the patients consult their pharmacist for OTC medications.^[65] A list of medications or OTC products most recommended by pharmacist^[66] can be viewed in Table 9. The pharmacist, who is the drug therapy expert, should and does play a large role in the counseling of patients on their OTC choices. Americans consume over \$50 billion nonprescription pain relief tablets each year to self-treat problems such as headaches, muscle aches, and arthritis. Many consumers do not bother to read the labels to prevent product misuse, they do not understand the risks or benefits of what they are taking, and many of them cannot

read the labels correctly. Patients may ask for recommendation to use an OTC from the pharmacist or even a nonprescription medicine by name. This familiarity with a product name does not imply that the patient has adequate knowledge about the drug. A survey done in 1998 by the APhA, which commissioned the Yankelovich study, to examine consumer attitudes and behavior regarding OTC medicines showed that among adult respondents 85% reported they have taken a nonprescription pain reliever at some point for pain and fevers, in fact one-third reported weekly use of these medicines.^[67] Forty-seven percent of all adults said that they do not always read medication labels; fewer than 40% consult pharmacists about these products; and over one-third said they were not aware of the risks associated with these medicines. Furthermore, 85% of the respondents said they had not heard of nonsteroidal anti-inflammatory drugs, or NSAIDs, which include aspirin and ibuprofen. When asked to name an NSAID, more adults mistakenly said APAP rather than aspirin. Of those surveyed, 74% did not associate stomach upset or bleeding with aspirin, and 43% were not aware of potential risks from taking an OTC pain reliever and prescription medication at the same time.^[67] These statistics point out the huge role for the pharmacist in the counseling and advising of OTC medications. As discussed previously, consumers have access to information about drug products through many avenues including the Internet, family members, and mass media. Some of this information may be very valuable but may also be erroneous. Consumers do not necessarily know about the side effects the drug may cause and the severity of the side effects nor are they aware of any contraindication to use, which can be pointed out during patient counseling. A study conducted by Sclar, Robinson, and Skaer^[68] has shown that consultation by final year pharmacy students resulted in almost 42% of the consumers changing their purchase decision. This resulted in a reduction in OTC medication expenditure by an average of U.S. \$1.53 per customer. This study also demonstrated that

**Table 9** List of some OTCs pharmacists recommend the most

Category	Most recommended product	Recommendation (%)	Number of recommendations/month for the category in general
Analgesics			
APAP	Tylenol	97	12
Aspirins	Bayer	80	9
Ibuprofens	Motrin	78	11
Ketoprofens	Orudis KT	86	4
Naproxen sodium	Aleve	96	6
Cough/cold/allergy			
Adult cold preparations	Comtrex	18	14
Children cold preparations	Dimetapp	44	11
Adult cough medications	Robitussin DM	47	14
Children cough medications	Triaminic	28	12
Allergy relief products	Chlor-Trimetom	44	13
Asthma relief products	Primatene	82	5
Flu remedies	Theraflu	51	8
Sinus remedies	Sudafed	45	11
Throat lozenges	Cepacol	20	8
Throat sprays	Chloraseptic	83	7
Gastrointestinal medications			
Antacids	Mylanta	55	7
Antidiarrheals	Imodium A-D	94	6
H2 antagonists	Pepcid AC	87	7
Hemorrhoidal preparations	Preparation H	69	4
Irritant or stimulant laxatives	Dulcolax	59	4
Topical dermatologicals			
Vaginal antifungals	Monistat	72	4

(From Ref. [66].)

the length of the consultation significantly influenced consumers to change their final purchase.

Pharmacist can help a patient know if there are any drug–drug or drug–food interactions with their OTC medications. A thorough medication history of both prescription and nonprescription medication including herbal supplements is a vital component to pharmaceutical care. By evaluating the medication history, the pharmacist can help the consumer make better-informed decisions concerning the purchase and use of nonprescription products. Additionally, the pharmacist has a responsibility to report to the patient's physician, the manufacturer, and the regulatory authorities for medicine, any relevant information about an adverse drug reaction encountered by the patient, which is associated with the purchase of a nonprescription medication.

In summary, the pharmacist has a significant role in assisting the consumer in their self-treatment. The pharmacist should assist the consumer in product selection, assess patient risk factors for OTC use, counsel the patient regarding proper drug use, maintain OTC medications on the patients medication profile, help the patient monitor themselves for toxicity and efficacy of the OTC medication, discourage the use of deceptive or

“quack” remedies, and prevent consumer delays in seeking appropriate treatment from other healthcare practitioners, if necessary. The pharmacist can make use of intervention strategies relating to patient/pharmacist interactions in the form of providing information, removing products from point of sale, sharing information with other local pharmacists, and making referrals to other members of the health care team.^[69]

FUTURE

The future of nonprescription medication clearly indicates growth. Americans will continue to rely on OTC medications as the most important aspect of self-care. Rx-to-OTC switches will continue to be a part of the drug industry's strategy to improve sales and increase consumer access to their products. With these continued changes there will arise the obvious problem of insurance coverage for OTCs. Most insurance companies do not cover OTC medications under their prescription benefits currently, but with increasing pressure from consumers and healthcare providers, this may change. Nonprescription medications, especially switched products, may become first line

Nonprescription Drugs

17

therapy in algorithms of patient care when dealing with managed care companies. The questions of reimbursement through medication copies are an issue that will certainly arise with insurance companies in time. With the new labeling requirements proposed by the U.S. FDA for OTC products, consumers should have a better knowledge regarding the medications they intend to take. However, the role of the pharmacist should continue to increase in the counseling of these products. With the vast amount of the population using these medications, new product availability, and the increasing interest in the American public in utilizing self-care, the pharmacist must focus their expertise on counseling and providing information to the public concerning these medications, which if used properly will have a large impact on our healthcare costs and satisfaction.

Trega Biosciences, Inc., San Diego, California, U.S.A.

OVERVIEW

Peptide and protein drugs have been increasingly utilized in the treatment of various diseases since recent dramatic advances in recombinant DNA and modern synthetic technologies have allowed for the cost-effective production of considerable quantities of protein pharmaceuticals. For the past several decades, major efforts have been directed toward developing effective means for the nonparental (i.e., noninvasive) delivery of protein pharmaceuticals. However, low bioavailability has limited the success of noninvasive delivery attempts (1–5). The primary reasons for low bioavailability include unfavorable physicochemical characteristics such as large molecular weight, charge, hydrophilicity, and physicochemical instability, and biological limitations such as poor membrane permeability, and presystemic enzymatic metabolism. Administration via these routes often requires specialized delivery systems, absorption enhancers, and/or proteolytic enzyme inhibitors to improve bioavailability. Various noninvasive routes of administration have been investigated and reviewed to deliver protein pharmaceuticals, including oral, mucosal-membrane, pulmonary, and transdermal routes (6, 7). To date, nearly all therapeutic proteins are administered by intravenous (IV), subcutaneous (SC), or intramuscular (IM) injection. A partial listing of protein pharmaceuticals in clinical use is shown in Table 1.

The only notable success in the noninvasive delivery of peptides or protein pharmaceuticals has been the oral delivery of small peptide drug analogs such as the penicillins, cephalosporins, ACE inhibitors, and renin inhibitors (8, 9). The intestinal absorption pathways of small peptides differ significantly from those for larger peptides and proteins. Smaller peptide drugs undergo carrier-mediated absorption by means of the human intestinal peptide transporters (hPepT1 and hPT1) (8–10). Peptides analogs with greater than three amino acid residues are not typically transported via the peptide

carriers, although the exact mechanisms of absorption have not yet been fully elucidated. The focus of this chapter is on the noninvasive delivery of larger peptide and protein pharmaceuticals. Some success has been achieved in the noninvasive delivery of protein pharmaceuticals, most notably in nasal delivery. Several examples of systemic protein delivery via noninvasive routes are described in this chapter. The chapter concludes with a focused discussion on strategies for the oral delivery of protein pharmaceuticals using a model small protein drug, salmon calcitonin (sCT).

NONINVASIVE ROUTES

Oral Delivery

The mucosal surface of the digestive tract is a vast area covered by a monolayer of epithelial cells joined by tight junctions that provide an effective barrier to absorption. The potential convenience and improved patient compliance associated with oral delivery have led to considerable research in this area. Some protein drugs have surprisingly good absorption characteristics. For example, the cyclic 11-amino acid compound cyclosporine has a relatively high bioavailability when properly formulated. Compared with the standard formulation (Sandimmune, Novartis, NJ), the microemulsion formulation (Neoral) increases the AUC and C_{\max} , and reduces t_{\max} , inpatient variability, and the effect of bile on cyclosporine absorption (11, 12). Oral absorption of cyclosporine from the Sandimmune formulation is shown in Fig. 1. With the exception of cyclosporine, very limited success has been achieved in delivering protein pharmaceuticals orally (Table 1). Detectable quantities of growth hormone, insulin, and calcitonin can be found in the systemic circulation after oral administration. However, the absorption of these drugs is highly inefficient. Typically, upward of 1000 times more drug is required

Table 1 Therapeutic polypeptide drugs and their clinical application

Therapeutics	Molecular weight (in Daltons)	Indications	Route of administration ^a
Alglucerase	59,300	Gaucher's disease	IV infusion
α-1 Antitrypsin	52,000	Congenital α-1 antitrypsin deficiency	IV infusion
Calcitonin	4500	Paget's disease, postmenopausal osteoporosis, hypercalcemia	IM, SC, intranasal
Cyclosporine	1200	Prophylaxis for allogeneic organ rejection	Oral, IV infusion
Desmopressin	1183	Intranasal: primary nocturnal enuresis IV Infusion: hemophilia A and von Willebrand's disease	Intranasal, SC, IV infusion
Dornase alfa	37,000	Cystic fibrosis	Inhalation
Erythropoietin	30,400	Treatment of anemia	SC, IV infusion
Etanercept	150,000	Rheumatoid arthritis	SC
Factor IX	55,000	Christmas disease	IV infusion
Filgrastim	18,800	Severe chronic neutropenia	SC
Glatiramer acetate	Average: 4,700–11,000	Multiple sclerosis	SC
Imiglucerase	60,430	Gaucher's disease	IV infusion
Insulin	Varies: minimum; 6000	Diabetes mellitus	SC, IV infusion
Interferon alfacon-1	19,434	Hepatitis C infection	SC
α-Interferon	19,271	Hairy cell leukemia	IM, SC
β-Interferon	22,500	Multiple sclerosis	SC
γ-Interferon	16,000–25,000	Reduce frequency of infections associated with chronic granulomatous disease	SC
Oxytocin	1007.2	Labor induction	IV infusion
Proleukin	15,300	Carcinoma	IV infusion
Retepase	39,571	Management of acute myocardial infarction	IV infusion
Sargramostim	Varies: 19,500, 16,800; and 15,500	Myeloid reconstitution	SC, IV infusion
Somatrem	22,000	Growth hormone	SC, IM
Streptokinase	47,000	Fibrinolytic	IV infusion
Thymosin α1 (Thymalfasin)	3108	Chronic hepatitis B	SC (currently in phase 3 studies)
Tissue plasminogen activator	70,000	Fibrinolytic	IV infusion

^a SC, subcutaneous; IM, intramuscular; IV, intravenous.

Fig. 1 Mean blood cyclosporine A (CsA) concentration (ng/ml)-time curves in 22 psoriatic patients (mean \pm SD) after a single IV administration of 2.5 mg/kg (IV infusion over 2 h with 0.5% solution of CsA in 0.9% NaCl) and after 1 week, oral administration of the same dose (Sandimmune, oral solution 100 mg/ml). The mean bioavailability was 44% (range, 22–63%). (From Galla, F.; Marzocchi, V.; Croattino, L.; Poz, D.; Baraldo, M.; Furlanut, M. Oral and Intravenous Disposition of Cyclosporine in Psoriatic Patients. *Ther. Drug Monitor.* **1995**, *17*, 302–304.)

to achieve the same effect after oral administration than when given by IV or SC injection. The oral delivery of protein drugs is critical for keeping health care costs low owing to enhanced compliance, reduced expenses compared with inpatient therapies, etc. The primary problems encountered with the oral delivery of protein pharmaceuticals include the poor intrinsic permeability owing to their hydrophilic nature and large molecular size, presystemic enzymatic metabolism by intestinal proteases and peptidases, chemical instability including tendencies to aggregate, and/or nonspecific binding to a variety of physical and biological surfaces. Because protein drugs are highly susceptible to all these factors, protein-delivery systems will have to simultaneously address all the issues to achieve higher bioavailability (13).

Although several approaches can be taken toward solving an oral bioavailability problem, the causes of incomplete bioavailability must first be understood. When poor membrane permeability is identified as a probable cause, approaches to formulate the drug with absorption enhancers that transiently modify biological membranes are used. Potential approaches to reduce presystemic metabolism include the transient modulation of the intestinal environment by limiting the activity of intestinal enzymes through the use of protease inhibitors (14); adjusting the local pH to values that correspond to the pH minima of specific enzymes present in the gut (15–17); maintaining high local drug concentrations to saturate

enzymes; regiospecific targeting because of regional differences in the activity of intestinal proteolytic enzymes, dilution, and spreading patterns; and surface area differences (18, 19). Other potential oral delivery approaches are chemical modification of proteins to produce prodrugs and analogs (20–22), substitution of D-amino acids to reduce hydrolysis (23, 24), and use of bioadhesive polymers that have a variety of mechanisms for enhancing protein drug absorption including inhibition of proteolytic enzymes or reducing the resistance of tight junctions (25).

Several attempts have been made to facilitate intestinal protein drug absorption by targeting specific absorptive transporter systems, such as the monosaccharide or bile acid transporters, or by modulating the secretory transport activity of *P*-glycoprotein (Pgp) (9). The coupling of unstable peptides with sugars has been demonstrated to improve hydrolytic stability and membrane permeability (26). Insulin has been modified with *p*-nitrophenyl- α -D-glucopyranoside and *p*-nitrophenyl- α -D-mannopyranoside. The coupling of these agents enhanced membrane permeation by an unknown mechanism and reduced the potential for enzymatic hydrolysis (27). In terms of modulating secretory transport, the intestinal absorption of some peptides that interact with Pgp, such as cyclosporine, tends to increase to some extent when efflux transporter inhibitors are used (28). Another delivery strategy includes the utilization of macromolecular ligands. Recently, the cellular and molecular mechanisms whereby macromolecules and particles are internalized have been studied (10). Although the use of endocytic pathways is currently highly inefficient, the mechanisms are being studied in cell culture models such as Caco-2 and Madin-Darby canine kidney (MDCK) cells in the hope of improving efficiency. By gaining a better understanding of how to target membrane transport mechanisms or modulate biological barriers, the oral bioavailability of protein drugs may be enhanced. Until then, the oral delivery of protein drugs will remain a considerable challenge for the foreseeable future, given the multiple biological obstacles that must be overcome to achieve therapeutic blood concentrations.

Mucosal Delivery

The high vascularity and accessibility of the mucosal membranes have made this tissue a potential route of protein delivery. Mucous membranes include the nasal, buccal, ocular, rectal, and vaginal membranes (29). Advantages of mucosal routes are that they bypass hepatic first-pass metabolism and are readily accessible, and locally acting agents such as penetration enhancers, enzyme inhibitors, and mucus-suppressing agents can be used.

Mucus is a highly viscous product that forms a protective coating over the lining of organs in contact with external media. Mucus is a mixture of large glycoproteins (mucins), water, electrolytes, sloughed epithelial cells, enzymes, bacteria and bacterial products, and various other materials, depending on the source and location of the mucus (30). Mucins are synthesized either by goblet cells lining the mucosal epithelium or by special exocrine glands with mucus cell acini. Mucoadhesive polymers have received considerable attention as platforms for protein drug delivery. Advantages include the ability to deliver drugs locally, prolong the residence time, and optimize contact with the absorbing surface to permit modification of tissue permeability to inhibit enzyme activity or to suppress mucus production (25–30). Bioadhesive bonds may be physical or mechanical bonds, secondary chemical bonds, or primary chemical bonds. Other approaches for mucosal protein delivery are formulating proteins in liposomes (7), microemulsions, and small particles (e.g., nanoparticles) (31, 32). The common rationale in all three cases is the protection of proteins from the local environment before to absorption and localization of the protein at or near the cellular membrane to optimize the driving force for passive permeation.

Nasal delivery

The nasal route has been intensively investigated because of its convenience (33). It presents a large surface area ($\sim 200 \text{ cm}^2$) that is lined by a single layer of columnar epithelial and goblet cells overlaying a rich blood supply. The extensive network of blood capillaries underneath the nasal mucosa provides an important part of the driving force required for the systemic delivery of proteins. Because the mucosal surface is covered by mucin that is cleared on a 15–30 min cycle, the residence time of solutions in the nasal mucosa is short. Therefore, mucoadhesive polymer solutions are typically required to increase the residence time. This route has been shown to be acceptable for peptides with 10 or fewer residues, whereas satisfactory bioavailability is obtained for proteins of 20 or more residues only when permeation enhancers are used (33).

The nasal mucosa contains enzymes capable of hydrolyzing peptides. The predominant enzyme appears to be aminopeptidase, among other exopeptidases and endopeptidases. The cytochrome P-450 activity in the olfactory region of the nasal epithelium is higher than in the liver (34). Phase II enzyme activity has also been found in the nasal epithelium (34). The metabolic cleavage of thyrotropin-releasing hormone (TRH) and met-enkephalin has been demonstrated in human nasal epithelial cell

Fig. 2 Mean serum salmon calcitonin (sCT) concentration (pg/mL)-time curve after intramuscular (IM) administration of 100 IU of sCT and intranasal (IN) administration of 100, 205, and 450 IU of sCT with 0.5% sodium tauro-24,25-dihydrofusidate (STDHF) in 10 healthy subjects (7 males, 3 females). Relative to the i.m. dose, the bioavailabilities of the i.n. formulations containing 0.5% STDHF were 3.9, 7.9, and 7.4%, respectively. The nasal calcitonin doses were administered as one 100- μ l spray per nostril using two single-dose spray units. sCT-STDHF formulations were prepared by reconstitution of solid sCT with a sterile isotonic (NaCl) solution of 0.5% STDHF in 20 mM acetate buffer, pH 5.0, and used immediately. (From Lee, W.A.; Ennis, R.D.; Longenecker, J.P.; Bengtsson, P. The Bioavailability of Intranasal Salmon Calcitonin in Healthy Volunteers with and without a Permeation Enhancer. *Pharm. Res.* **1994**, *11*, 747–750.)

monolayers, suggesting that the nasal mucosa may be a significant metabolic barrier to the systemic delivery of protein drugs (35). Permeation enhancers and protease inhibitors are usually coadministered to achieve successful delivery of proteins by this route. Intranasal absorption of salmon calcitonin is demonstrated in Fig. 2. Relative to the IM dose, the bioavailability of intranasal (IN) administration of sCT was low, 3.9–7.9%. When eel calcitonin (eCT) was coadministered with nafamostat mesilate, a protease inhibitor, or with sodium decanoate, the sodium salt of fatty acid, the nasal absorption of eCT was significant, and serum calcium (Ca^{2+}) concentration was effectively decreased (36). Several nasal products have been available clinically including buserelin, desmopressin, oxytocin, and calcitonin (29).

Buccal delivery

Delivery of protein drugs through the buccal mucosa has also received considerable attention (37). Despite its apparent disadvantages, such as limited absorptive surface area and moderate mucosal permeability, the buccal route might be acceptable for small- or medium-sized peptide drugs. Potential advantages for buccal delivery are the

avoidance of gastrointestinal (GI) or hepatic first-pass metabolism, the feasibility of locally controlled absorption enhancement, the ease of administration and removal of an administered device, and the possibility of prolonged drug delivery and action. The buccal epithelium has an average thickness of 500–600 μm . The epithelial cells at the outer surface are continuously peeled off because of abrasion that occurs during mastication. Therefore, starting from nondifferentiated cells located above the basal membrane, fresh epithelial cells are produced by mitosis. During their 5- to 8-day passage from the basal membrane to the outer surface, the epithelial cells undergo maturation resulting in a change in form and size.

The buccal cavity exhibits greater proteolytic enzyme activity than does the nasal or vaginal mucosa. The metabolic activity is shown to reside primarily in the epithelium (38). A mucoadhesive buccal patch was evaluated in rabbits for transmucosal delivery of oxytocin (OT) after incorporation into custom coformulations of Carbopol 974P and silicone polymer (39). It was observed that plasma OT concentrations remained 20- to 28-fold greater from 0.5 to 3.0 h than concentrations in control animals administered placebo patches. Several transmucosal therapeutic systems (TmTs) were also investigated to study the enhanced/controlled delivery of leuteinizing hormone-releasing hormone (LHRH) in dogs (40). The TmTs is a track field-shaped bilayer mucoadhesive device consisting of fast- and sustained-release layers. A stream of 0.5–2 L of saliva constantly washes the oral cavity daily. The resulting salivary layer covering all oral epithelia can interfere with the penetration of drugs as well as with the adhesion of buccally administered delivery devices. Therefore, several factors must be considered in designing buccal dosage forms—the taste of drugs and excipients, the size of the dosage form, and the mechanism for fixing the dosage form onto the oral mucosa. Nevertheless, even under optimized conditions, the buccal delivery of proteins may not allow for bioavailabilities as high as that with other mucosal sites. Thus, the chances for buccal protein delivery, if any, will be restricted to special cases and for special proteins of high permeability. In this instance, however, buccal delivery might be a preferred route of administration, mainly owing to the undisputed acceptance and compliance of oral dosage forms and to the unmatched robustness of the epithelium.

Ocular delivery

The ocular route has been investigated for the systemic delivery of protein drugs (41, 42). Systemic absorption of proteins after topical administration to the eye results through contact with the conjunctival and nasal mucosa, the latter occurring as a result of the drainage through the

nasolacrimal duct. When systemic absorption is desired, absorption through the conjunctival and nasal mucosa needs to be maximized. The systemic delivery of proteins through the ocular route has several advantages including convenience, rapid absorption/onset, and avoidance of hepatic first-pass metabolism, and it is amenable to controlled-release delivery. However, this route typically yields low bioavailability, although it is well accepted by patients. As with other delivery routes, the size, charge, and hydrophilic nature of proteins are the primary determinants that limit their extent of absorption. Because the systemic delivery of proteins depends on their transport mechanisms and contact time with mucosal membrane of the conjunctiva and the nasolacrimal system (43), the following factors need to be considered: 1) precorneal factors such as tear drainage, instilled volume, viscosity, pH, and tonicity; 2) that the eye formulations used must avoid the potential for local irritation and/or side effects; and 3) that inclusion of permeation enhancers may be necessary when dealing with agents with a molecular weight higher than 10,000 Da.

Systemic delivery of insulin and glucagon through the ocular route was demonstrated as a feasible alternative to parental injection, particularly when permeation enhancers were added (44).

Rectal delivery

The rectal epithelium is columnar or cuboidal, with numerous goblet cells. However, unlike the small intestine, the rectal epithelium does not contain villi. The human rectum has a length of 5 inches and a surface area of only approximately 200–400 cm^2 , compared with 2,000,000 cm^2 for the small intestine. Consequently, absorption from the rectum could be much lower than from the remainder of the GI tract (45). The lower venous drainage system (inferior and middle hemorrhoidal veins) is connected directly to the systemic circulation by the ileac vein and vena cava, whereas the upper venous drainage system (superior hemorrhoidal vein) is connected to the portal vein system. Thus, an opportunity to reduce the extent of hepatic first-pass elimination exists in the rectum. The rectum also has a large number of lymphatic vessels that offer an opportunity to target drug delivery to the lymphatic circulation.

Extensive studies have been conducted regarding the rectal absorption of proteins, especially insulin. However, the rectal absorption of this drug is low, probably owing to a combination of poor membrane permeability and metabolism at the absorption site (46). Therefore, it is generally believed that absorption enhancers are required to achieve therapeutic plasma levels of rectally administered proteins. The rectal route can be an

extremely useful route for the delivery of drugs to infants and young children in whom difficulties can arise using per oral administration. Historically, the rectum has not been an accepted site of drug delivery. Its principal applications have been for local therapy, e.g., hemorrhoids, and for systemic delivery of drugs to populations presenting practical problems for parenteral or oral dosing (e.g., the elderly, infants, patients with epilepsy, etc.). Even though the systemic delivery of peptide can occur by this route, it is not widely accepted among the populations of the world.

Vaginal delivery

The vaginal wall consists of an epithelial layer (epithelial lamina and lamina propria), muscle layer, and tunica adventitia. It is regulated by cyclic alteration of the reproductive system, which is directly controlled by hormones such as estrogen, progesterone, leuteinizing hormone (LH), and FSH (45). Before puberty, the epithelium is very thin, but after puberty, it increases in thickness with estrogen activity. In the adult stage, the vaginal surface during the follicular phase appears homogeneous with large superficial polygonal cells with a high degree of proliferation caused by estrogen stimulation and the presence of cornification. This proliferation of cells concomitantly increases the epithelial thickness and number of layers. The lamina propria specialized supporting structure of the epithelial cells contains a blood supply, a lymphatic drainage system, and a network of nerve fibers. The vaginal epithelium is aglandular but is usually covered with a surface film of moisture. The pH of the vaginal lumen is controlled mainly by the lactic acid produced from cellular glycogen by the action of the normal microflora, Doderlein's bacilli. The arterial blood supply in the vagina is derived from the visceral branches of the internal iliac artery, and venous drainage occurs mainly via the uterine vein to the internal iliac vein.

It is known that several peptide hormones and antigenic proteins are absorbed intact through the vaginal membrane and that the bioavailability is greater than that by the oral route because of higher intercellular permeability and reduced first-pass metabolism. The amount and duration of the hypoglycemic and hypocalcemic effects induced by intrauterine delivery of insulin and calcitonin, respectively, were equivalent to those obtained after s.c. injections in intact and ovariectomized rats (47). Regarding the enzymatic barrier, few enzymes have been found in the vaginal epithelium and in the peptidase activity against enkephalins, substance P, insulin, and proinsulin in the absorptive mucous membranes in the rabbit. In fact, supernatants of homogenates of the vaginal, nasal, buccal, rectal, and ileal mucous membranes of

rabbit exhibit similar proteolytic activity (46). Vaginal delivery of sCT was demonstrated effectively in ovariectomized rats using the highly mucoadhesive polymer, the benzyl ester of hyaluronic acid (Hyaff 11), by closely adhering to the mucosal surface and by protecting the drug from enzymatic inactivation (48). Most of the vaginal preparations on the market are used for local action on the vaginal membrane, using antibacterial, antifungal, or antiviral agents.

Pulmonary Delivery

Pulmonary delivery provides an attractive route of administration for systemic protein delivery. Of all the noninvasive routes for protein delivery, the pulmonary route has provided the most encouraging data and has recently generated great interest in the biotechnology industry (49, 50). Advantages of the pulmonary route include the fact that the walls of the alveoli are thinner than are other epithelial/mucosal membranes, that the surface area of the lung is much greater, and that the lungs receive the entire blood supply from the heart. Of course, the lungs are rich in enzymes, and overcoming this barrier is no easy task. Peptide hydrolases, peptidases, and a wide variety of proteinases are present in lung cells. The respiratory tract has several unique features (51): 1) a large surface area that can be exposed to drug almost simultaneously as opposed to the intestine, which has a similar total surface area but does not allow for simultaneous exposure; 2) a high blood flow that does not directly expose absorbed drug to the clearance mechanisms present in the liver; and 3) relatively less metabolic activity.

The upper respiratory tract, including the trachea and large bronchi, has a relatively limited surface area for absorption compared with the alveolar region, which provides more than 95% of the surface area of the lung. The respiratory tract is lined on its luminal surface by a layer of columnar epithelial cells that become progressively less columnar in the smaller airways and alveolar region. The surface of the airway epithelial cells in the larger conducting airways is covered with cilia that aid in the clearance of material from the lung. Two types of epithelial cells are present in the alveolar region of the lung: the type I and the type II pneumocytes. Type I cells are flat cells with broad, thin extensions covering up to 95% of the alveolar surface, whereas type II cells are cuboidal cells without extensions that can differentiate into type I cells and participate in the repair of the epithelial cell surface after damage. The alveolar epithelium is assumed to be the site of protein delivery, based on surface area considerations. The passages leading to the lower lung from the nasal region are narrower than

the oral passages. This allows for much more efficient filtration and much less efficient delivery after nasal administration and has led to the development of a variety of devices that deliver aerosols via the mouth. Dry and liquid particles can be prepared and inhaled with the aid of dry powder dispensers, liquid aerosol generators, and nebulizers. These devices produce particles that range from 1 to 5 μm , which may penetrate deeply into the alveoli of the lung. Once deposited deep in the lung, the alveoli provide a large surface area (80–140 m^2) for rapid transfer into the pulmonary circulation.

In the literature, molecules ranging to greater than 100,000 Da have been demonstrated to be appropriate candidates for pulmonary delivery. Several proteins are currently under investigation for systemic delivery, including insulin, calcitonin, leuteinizing-hormone-releasing hormone (LHRH) analogs, granulocyte colony-stimulating factor (gCSF), and human growth hormone (hGH). Inhalation of regular insulin for meal time (i.e., postprandial) glucose control has been found to be safe, efficacious, and reliable in type I and type II diabetes patients (52). Compared directly with s.c. injection, inhaled insulin provides equivalent glucose control. A potential advantage of aerosol insulin is that it is more rapidly absorbed (serum peak at 5–60 min) and cleared than SC injection (peak at 60–150 min), which provides a more relevant and convenient therapy for mealtime glucose control. Deftos et al. (53) have evaluated the intrapulmonary (IP) delivery of sCT in normal subjects with a dry powder inhaler. Compared by dose, i.p. sCT had 66% of the bioactivity and 28% of the bioavailability of intramuscular (IM) sCT (Fig. 3).

Transdermal Delivery

Considerable effort has been given to the transdermal delivery of pharmaceutical proteins, but clinical applications have thus far been limited to nonprotein drugs (54). The skin is impermeable to molecules as large as proteins. The physical (stratum corneum) and proteolytic enzymatic barriers create a formidable barrier against any permeation under normal circumstances. A molecular size of approximately 1000 Da is generally believed the molecular size limit for transdermal delivery, but there are some reports on the permeation of macromolecules across the stratum corneum by passive diffusion. In addition to molecular size, the lipid-protein partition coefficient of the penetrant is very important. The skin also consists of an enzymatic barrier capable of metabolizing proteins. The composition of enzymes and the spectrum of metabolic reactions in the skin are similar to those in the liver, although the skin

Fig. 3 Mean serum salmon calcitonin (sCT) concentration (pg/ml)-time curves after intramuscular (IM) administration of 100 IU of sCT and intrapulmonary (IP) administration of 160 or 320 IU of sCT in 10 normal males. sCT was administered with a dry powder-delivery inhaler. Dosage adjustments were made by dividing serum sCT concentrations by dose units. The apparent concentration of sCT at time zero represents assay blank in an RIA method. There were no additional substantial changes in sCT after 120 min. Compared by dose, IP sCT had 66% of the bioactivity and 28% of the bioavailability of IM sCT. (From Ref. 53.)

has significantly less metabolic activity than does the liver (55).

Various strategies have been attempted to surmount these barriers. These include the use of protease inhibitors to suppress enzymatic activity and the use of penetration enhancers to reversibly reduce the barrier resistance of the stratum corneum. Other alternatives include forced delivery under an electric field (iontophoresis) and ultrasonic energy (phonophoresis), but their efficacy has been limited by the large size and relatively low electrical charge of proteins. Green et al. (56) and Singh et al. (57) review iontophoresis.

Iontophoresis generates an electrical potential gradient that facilitates the movement of solute ions across the membrane and has been used with the greatest success in the treatment of hyperhidrosis. However, iontophoresis is capable of delivering large hydrophilic proteins in a continuous manner over a prolonged period because of their charged nature. Human studies have been performed to demonstrate the safe, effective, and reproducible delivery of a positively charged calcitonin analog with a molecular weight of approximately 3000 to the systemic circulation (Fig. 4). Some success has been reported in delivering peptides such as antinflamin 1 by iontophoresis (58). It has also been reported recently that proteins as large as insulin (~6000 Da), interferon γ (~17,000 Da), and erythropoietin (~30,400 Da) could be delivered

Fig. 4 Mean plasma calcitonin concentration (pg/ml)-time curve resulting from 6-h iontophoretic delivery ($n = 12$) of a calcitonin analog peptide in healthy male volunteers. Plasma levels obtained from IV infusion for 6 h (80 IU, $n = 8$) and IM injection (80 IU, $n = 11$) of the peptide are also shown. Plasma concentration time-profiles indicate that steady-state plasma levels are achieved rapidly, and the decline in plasma levels appears to be absorption-limited rather like an i.m. injection. However, short lag times are observed, which are consistent with diffusion across the outermost layers of the skin but shorter than those typically associated with passive transdermal diffusion. The active and placebo iontophoretic treatment patches were applied at a current density of $200 \mu\text{A}/\text{cm}^2$ for a 6-h period. Blood samples were removed for pharmacokinetic assessment at the start of dosing and at regular intervals during and after treatment. Plasma samples were assayed using an RIA method. (From Ref. 56.)

across the skin at therapeutic concentrations with the aid of low-frequency ultrasound (58).

ORAL DELIVERY STRATEGIES

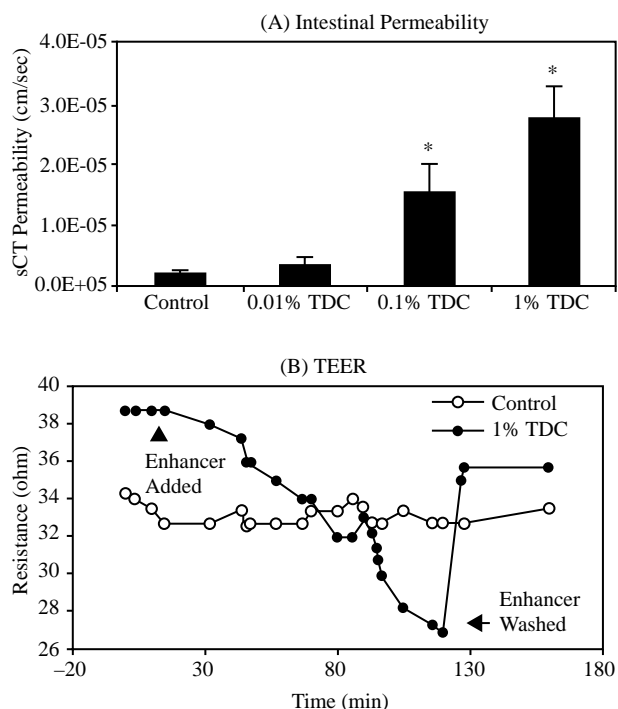

The remainder of this chapter focuses on strategies for improving the oral bioavailability of protein pharmaceuticals and, in particular, describing our experiences with salmon calcitonin. sCT is an endogenous polypeptide hormone composed of 32 amino acids that plays a crucial role in both calcium homeostasis and bone remodeling (59, 60). Four forms of CT are used clinically, namely synthetic human CT, synthetic salmon CT, natural porcine CT, and a synthetic analog of eel calcitonin. Currently, CT is administered parenterally or nasally (61, 62). To effectively inhibit the manifestations of metabolic bone disorders such as Paget's disease and osteoporosis, a frequent and relatively high dosage of CT is administered (63). The oral route is a preferred route of administration, considering the chronic nature of CT therapy. However,

because of extensive proteolytic degradation in the GI lumen and low intrinsic intestinal membrane permeability, insufficient oral bioavailability (BA) of CT necessitates the use of high doses (4000 to 6000 IU/mg) of sCT, even though sCT is 20–30 times more potent than hCT (150–200 IU/mg) (64–66). The unique structure of sCT protects it against its sequestration and metabolism in the liver (67). In this chapter, several approaches for enhancing the oral absorption of sCT are presented. sCT delivery systems for the treatment of osteoporosis are reviewed for many routes including nasal, transdermal, ocular, oral, bronchial, rectal, and vaginal administration (68).

Permeation Enhancement

The poor intrinsic permeability of proteins across biological membranes is well documented (1, 2, 4, 69) and can generally be attributed to their hydrophilic nature and large molecular size. Membrane carrier systems that facilitate the absorption of small peptides (di- and tripeptides) are not efficient at transporting larger peptides and proteins. Permeation enhancers have received considerable attention in attempts to modify the basic barrier properties of the intestinal epithelial cell membrane. Various classes of formulation additives including bile acids, salicylates, fatty acids, acylcarnitines, surfactants, medium chain glycerides, and chelating agents have been studied as absorption enhancers. Each of these agents exerts its enhancing effects by different mechanisms, and each has been associated with adverse effects (70).

Recently, we published in vitro and in vivo results of the evaluation of the performance of formulation additives to enhance the intestinal uptake of sCT (71). The effect of formulation additives on sCT effective permeability (P_{eff}) and transepithelial electrical resistance (TEER) was evaluated in side-by-side diffusion chambers using rat intestinal segments. Various additives such as sodium taurodeoxycholate (TDC), sodium taurocholate, sucrose stearate, sucrose ester-15, Tween 80, lauroyl carnitine chloride (LCC), myristoyl carnitine chloride, cetyl pyridinium chloride, and cetrimide were evaluated in rat jejunum at concentrations ranging from 0.01 to 1%. The effective permeability of sCT was greatest in the presence of TDC ($2.73 \pm 0.54 \text{ E-5 cm/s}$), increasing up to 14 times over the control ($1.91 \pm 0.45 \text{ E-6 cm/s}$) in a concentration dependent manner (Fig. 5A). The permeability enhancement relative to control was 5 times for LCC, 3.9 times for Tween 80, 3.2 times for sodium taurocholate, 2.6 times for myristoyl carnitine chloride, 2.3 times for sucrose stearate, 2.0 times for cetyl pyridinium chloride, 1.7 times for sucrose ester-15, and 1.3 times for cetrimide at 1% additives. The order of enhancement on the basis of

EC_{50} values (concentration of enhancer for 50% enhancement) was TDC, LCC > sodium taurocholate > tween 80 > myristoyl carnitine chloride > sucrose stearate > sucrose ester-15 > cetyl pyridinium chloride > cetrimide. After the exposure to various additives such as TDC, LCC, and cetrimide at concentration ranging from 0.1 to 1%, the TEER was reduced in a concentration- and contact time-dependent manner for all additives, whereas the TEER increased when the tissue was washed free of additives (Fig. 5B). When 1% formulation additives were washed after approximately 100 min exposure, the TEER returned to 92% of the initial value for TDC and approximately 80% of initial value for the others. As demonstrated during the in vitro and in vivo evaluation of formulation additives, the oral absorption of protein drugs can be maximized by balancing permeability increases and the toxic effects associated with the use of enhancers.

The effect of formulations on the intestinal bioavailability of sCT was studied in an intestinal and vascular access port (IVAP) dog model (71). A schematic representation of the IVAP dog with four ports in the duodenum (ID), ileum (IL), colon (IC), and portal vein (PV) is shown in Fig. 6. The regional (jejunal and ileal) bioavailabilities from formulations DDS1 and DDS2 [DDS1 and DDS2 contained sCT, citric acid (CA), and lauroyl carnitine chloride (LCC) or sodium taurodeoxycholate (TDC), respectively] were significantly

Fig. 5 (A) Plot of effective permeability (sm/s) of sCT in rat jejunum (mean \pm SD; $n = 3$). Effect of TDC was investigated at various concentrations ranging from 0.01 to 1%. * indicates the significant difference from control by $P < 0.05$. Side-by-side diffusion chambers were used. The exposed tissue surface area was 0.636 cm^2 and the volume of each half-chamber was 1.7 ml. Mixing in the chambers was controlled using a gas lift mechanism. The temperature was maintained at 37°C throughout the experiment. A 1.5- to 2-cm strip of rat intestinal tissue was excised from the animals, rinsed free of luminal contents using Ringer's buffer (pH 7.4), and mounted onto a diffusion half-chamber maintained at 37°C . Tissues were bathed in 15 mM Mes Ringer's buffer containing $50 \mu\text{M}$ of sCT with or without formulation additives on the mucosal side (pH 5, 290 mOsm/kg) and Ringer's buffer without additives on the serosal side (pH 7.4, 290 mOsm/kg). Small aliquots (0.5 ml) were taken from the serosal chamber at 30, 45, 60, 75, 90, and 105 min and analyzed by RIA. The effective permeabilities were calculated from the experimental data using the following equation based on Fick's First Law: $P_{\text{eff}} = (V_r/A \cdot C_0) \cdot dC/dt$ where V_r is the volume of the receiver chamber, A is the absorbing surface, C_0 is the initial drug concentration in the donor (mucosal) phase, and dC/dt is the change in drug concentration in the receptor (basolateral) phase per unit of time. In the presence of TDC, the effective permeability of sCT ($2.73 \pm 0.54 \text{ E-5 cm/s}$) was increasing up to 14 times over the control ($1.91 \pm 0.45 \text{ E-6 cm/s}$) in a concentration-dependent manner. (B) Transepithelial electrical resistance (TEER, ohm) versus time curves with or without 1% TDC in rat jejunum. Chambers connected to a voltage-current clamp for measuring transepithelial electrical resistance (TEER) of the intact tissue. The exposed tissue surface area was 1.5 cm^2 , and the volume of each half-chamber was 7 ml. Rat intestinal tissue was mounted in chambers, and then two sets of Ag/AgCl electrodes were connected to the voltage-clamp system to pass the current through the membrane. Tissues mounted in chambers usually required approximately 20 min for reaching temperature and TEER equilibrium. Experiments with formulation additives were not initiated until this time. The mucosal strips were then exposed to formulation additives at concentrations ranging from 0.01 to 1% at pH 4 Mes Ringer's buffer. After the initial equilibrium period, TEER was measured and subsequently recorded at regular time intervals. To determine the reversibility of additive effects on TEER, the buffer was replaced with fresh buffer without additives, and the TEER was monitored until a stable reading was observed. When 1% formulation additives were washed after an approximate 100-min exposure, the TEER was returned to 92% of initial value for TDC. (From Ref. 71.)

greater than their respective controls. Bioavailability enhancement ranged from 98 to 337% for all treatments and regions studied. Compared which sCT alone (without CA), bioavailability enhancement ranged from 1220 to 3070% for DDS1 or DDS2. The in vivo augmentation of sCT absorption by DDS1 or DDS2 correlated well to the in vitro permeation enhancement (Fig. 7).

Fig. 7 The plot of in vitro effective permeability (P_{eff}) of sCT in rats (mean \pm SD; $n = 3$) versus in vivo absolute bioavailability of sCT formulation in intestinal and vascular access port (IVAP) dogs (mean \pm SD; $n = 5$ to 6). The in vitro diffusion study was carried out in side-by-side diffusion chambers at concentrations equivalent to the dilution of sCT control and DDS formulation ingredients in 50 ml of buffer solution. DDS1 contains sCT, CA, and LCC, and DDS2 contains sCT, CA, and TDC. The in vivo intestinal bioavailability experiment of formulations was carried out in an IVAP dog model at concentrations of sCT and DDS additives in 5 ml of buffer solution. The ports for IVAP infusions were accessed transcutaneously with a 22-G Huber needle. It was observed that formulations containing TDC or LCC had a significantly higher effective permeability compared with their respective controls. The enhancement in the ileal segment was significantly higher than in the jejunal segment for DDS1 and DDS2. Bioavailability enhancement ranged from 98 to 337% for all treatments and regions studied. The in vivo augmentation of sCT absorption by DDS1 or DDS2 correlated well to the in vitro permeation enhancement. (Reproduced from Ref. 71.)

Protection from Enzymatic Degradation

The susceptibility of proteins to enzymatic attack is well known and remains a major challenge of oral delivery (1, 3, 4, 72–73). Yamamoto et al. (74) reported that various protease inhibitors, including sodium glycocholate, camostat mesilate, and bacitracin, can increase the glucose-lowering activity of insulin administered to rat intestine and colon, apparently by inhibiting protease activity in the lumen and mucous layer of the intestinal tissue. The degradation of calcitonin is also decreased in the presence of protease inhibitors such as camostat and aprotinin (75). The mucoadhesive polymers polycarbophil and carbomer, approved by the U.S. FDA, may have potential for protecting peptides from tryptic degradation by immobilizing trypsin under the depletion of Ca^{2+} (76).

Another potential approach to minimize the activity of intestinal enzymes includes adjusting the pH of the intestinal contents to the corresponding pH minima for proteolytic enzyme activity. Several laboratories have shown that proteolytic activity against insulin, calcitonin, and insulin-like growth factor-I was completely inhibited by pH-lowering mechanisms using polyacrylic acid

polymer (16, 17). We recently used traditional pharmacokinetic techniques combined with radiotelemetric measurement of intestinal pH to elucidate the effect of pH modulation on the oral absorption properties of sCT (77). Studies were performed to characterize the disintegration of the formulation, intestinal pH changes, and the appearance of the peptide in the blood. Enteric-coated formulations containing sCT and various amounts of citric acid (CA) were tethered to a Heidelberg capsule (HC) and given orally to normal beagle dogs (Table 2).

Table 2 The composition of sCT enteric capsules tested in beagle dogs

Formulations	sCT (mg)	CA (mg)	LCC (mg)	Talc (mg)	Dextrose (mg)
97B	1.11	0	55.2	55.2	552.4
97C	1.20	145.7	54.7	54.7	400.7
97D	1.15	260.2	51.9	52.2	260.5
97E	1.19	565.1	56.3	56.3	0

CA; citric acid; LCC, lauroyl carnitine chloride.

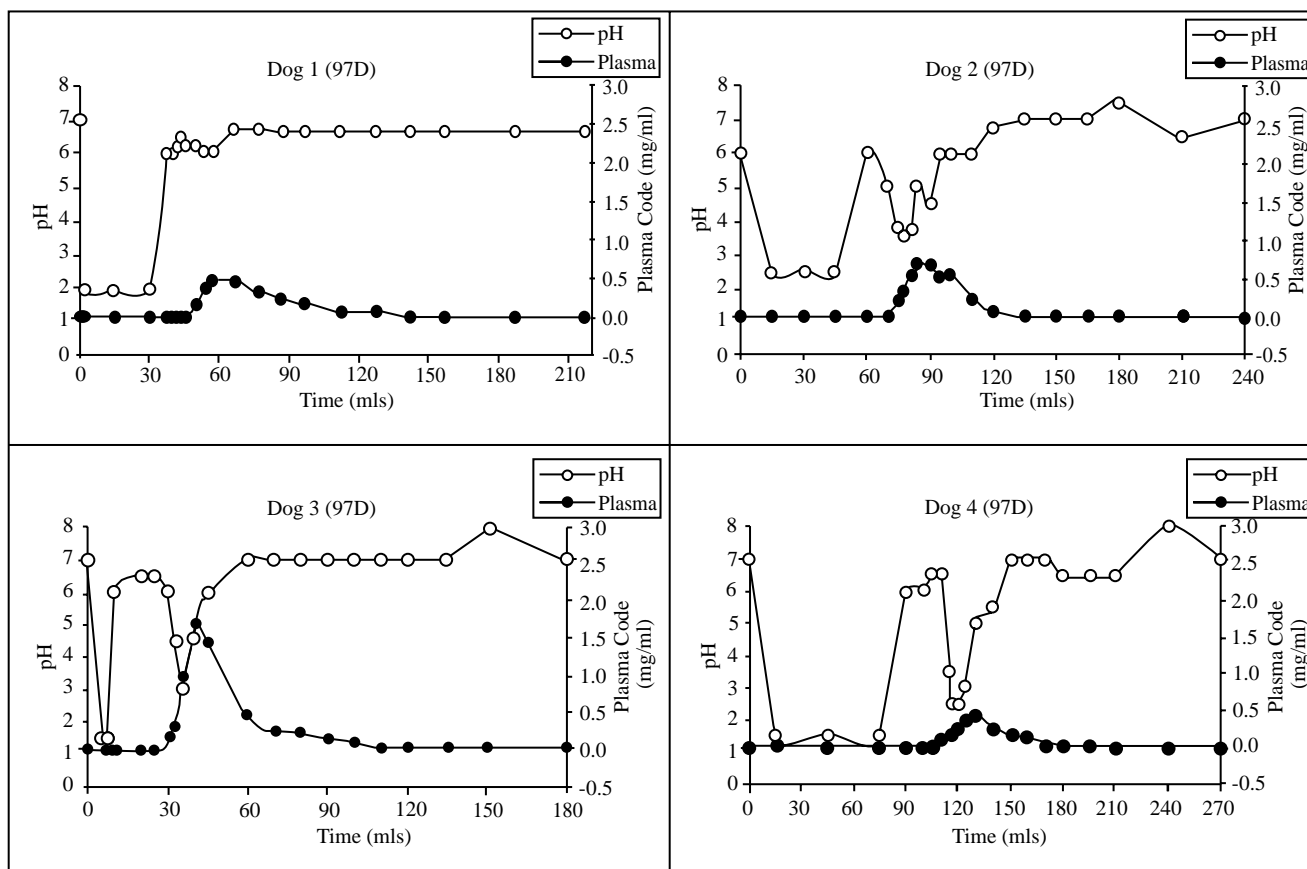

Fig. 8 The pH and plasma sCT concentration-time profiles after oral administration of formulation 97D (containing 1.15 mg of sCT, 260.2 mg of CA, 51.9 mg of LCC, 52.2 mg of Talc, and 260.5 mg of dextrose) (Table 2) tethered to a Heidelberg capsule in normal beagle dogs. Continuous determination of pH was accomplished using a radiotelemetric device, the Heidelberg capsule (HC). The device consists of a battery-operated, high-frequency radio transmitter and a pH electrode housed in a nondigestible acrylic capsule 7 mm in diameter and 20 mm in length. The dogs wore an antenna strapped around the body to receive the radio signal that was then recorded on a chart recorder. The capsule battery was activated with normal saline and calibrated in pH 1 and pH 7 buffer solutions maintained at 37°C. The HC was then tethered to the drug capsule using surgical thread (3-0 vicryl) and administered orally to dogs. Because pH values change with location within the gut and the drug capsule dissolution, alterations in pH were interpreted to be indicative of the movement of the HC-drug capsule through the different segments until the drug capsule dissolves. Generally, Heidelberg capsules provide readings with ± 0.5 pH unit accuracy and excellent in vivo reproducibility in the pH range of 1–8 for 22 h after activation. Four male beagle dogs were used to monitor the disintegration and oral absorption of sCT formulation 97D. An HC tethered to an enteric capsule was given orally with 10 ml of water to each dog. Two baseline blood samples were drawn before to dosing and another immediately after gastric emptying (GE). From the time the capsules enter the small intestine, blood samples were taken every 10 min until the HC showed a drop in pH, which signified the disintegration of the test capsule. More frequent blood sampling was performed from the time that disintegration was first detected, with blood samples taken at 3, 6, 9, 12, 15, 20, 30, 45, 60, 75, 90, 120, 150, and 180 min. The peak plasma concentrations of sCT were always observed when the intestinal pH declined. (Reproduced from Ref. 77.)

Blood samples were collected and analyzed using radioimmunoassay (RIA). Intestinal pH was continuously monitored using the HC system. The intraindividual variation in gastric emptying (GE) of the delivery system was large. There were large interindividual differences in the disintegration and absorption properties. However, the peak plasma concentrations of sCT were always observed

when the intestinal pH declined (Fig. 8). The intestinal pH decrease was not observed when CA was not included, but an intestinal pH decrease was obvious in all formulations that included CA. The intestinal pH was significantly affected by the amount of CA in the formulations. Plasma concentrations of sCT were observed in all formulations that included CA, but plasma concentrations of sCT were

Fig. 9 The plasma C_{\max} (A) and AUC (B) of sCT after oral administration of various formulations (Table 2) in normal beagle dogs. Data are expressed mean \pm SEM ($n = 3$ to 4). Formulation 97E was significantly different from 97B(1), 97C(2), and 97D(3) by $P < 0.05$ using one-way ANOVA. By increasing the amount of CA in the formulation, the oral absorption of sCT increased gradually. (Reproduced from Ref. 77.)

not observed in formulation 97B in which CA was not included (Table 2). There was a good correlation between the time to reach the trough intestinal pH ($t_{\text{pH,min}}$) and time to reach the peak plasma concentration ($t_{\text{conc,max}}$) of sCT ($t_{\text{conc,max}} = 0.95 \times t_{\text{pH,min}} + 14.1$, $n = 11$, $r^2 = 0.91$). As a consequence, the intestinal pH decrease caused by CA appears to be critical for the oral absorption of sCT. By increasing the amount of CA in the formulation, the oral absorption (C_{\max} and AUC) of sCT increased gradually (Fig. 9). These results indicate that the oral absorption/or enhancement of sCT absorption is directly related to the stabilization of sCT by a reduction in intestinal pH. The pH stability of pancreatic trypsin (human) is optimal at pH 5–6. At pH 4.0, approximately 45% of the activity remained, whereas 15% of activity was retained at pH 3.5 (78). As evidenced in this study, reducing intestinal pH resulted in a significant improvement in sCT absorption.

Another approach to providing protection against proteolytic attack, rather than enzyme inhibition, has been to protect proteins in the physical environment

of the formulation itself. In recent years, significant efforts have been directed toward formulating proteins in microemulsions, small particles (e.g., nanoparticles), and bioadhesive particles (31, 32). The rationale in all three cases is often similar: protection of proteins from the intestinal environment before absorption and localization of the protein at or near the cellular membrane to optimize the driving force for passive permeation. Pegylation of a therapeutic protein may be a suitable form of the protein

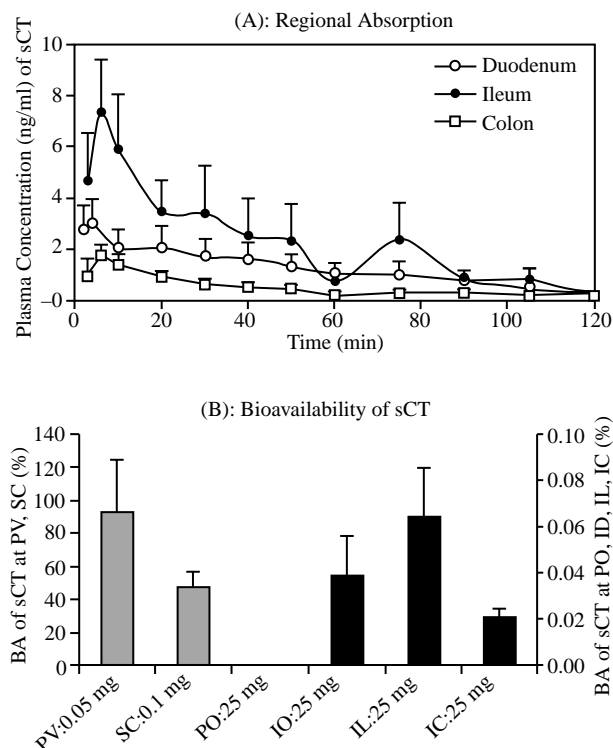

Fig. 10 (A) Plasma concentration (mean \pm SEM) of sCT versus time curves after bolus duodenal, ileal, and colonic administration in intestinal and vascular Access port (IVAP) dogs ($n = 5$ to 6). The ports for IVAP infusions were accessed transcutaneously with a 22-G Huber needle. The sCT formulation (25 mg/5 ml/dog) was infused rapidly (12 ml/min), and the port was cleared with a final flush of 1 ml of sterile water. Blood samples were drawn at 1, 3, 6, 9, 12, 15, 20, 30, 45, 60, 75, 90, 120, 150, 180, and 240 min. Absorption of sCT from the ileum was better than from the other regions studied. (Reproduced from Ref. 71.) (B) Bioavailability of sCT (mean \pm SEM) after portal venous (pv 50 μ g), subcutaneous (sc 100 μ g), and oral (po), duodenal (ID), ileal (IL), and colonic (IC) administration of 25 mg sCT in IVAP dogs ($n = 4$ to 6). The BA (mean \pm SD) of unformulated sCT was $92.8 \pm 32.0\%$ for portal vein, $47.5 \pm 9.3\%$ for subcutaneous, 0% for oral, $0.039 \pm 0.017\%$ for duodenal, $0.064 \pm 0.022\%$ for ileal, and $0.021 \pm 0.004\%$ for colon. The hepatic extraction of sCT is negligible in IVAP dogs.

in an oral-delivery formulation (79). Recombinant human granulocyte colony stimulating factor (PEG-gCSF) resulted in an increase in stability and in retention of in vivo bioactivity when administered by the intraduodenal route. Another reported approach uses mucoadhesion of nanoparticles having surface hydrophilic polymeric chains (80). In that report, it was observed that there was a good correlation between mucoadhesion and enhancement of sCT absorption in rats. The GI transit rates of nanoparticles having surface poly(*N*-isopropylacrylamide), poly(vinylamine), and poly(methacrylic acid) chains were reduced, and sCT absorption was improved. Temperature and pH-sensitive polymers for hCT delivery are also reported (81). Stimuli-sensitive polymers are suitable candidates for oral delivery vehicles because they will prevent gastric degradation in the stomach while providing a controlled release of a peptide drug. The beads made of the polymers with a high content of acrylic acid (most hydrophilic) provided better loading, stability, and release of hCT. In vivo biological activity of the released hCT was preserved.

Maintaining High Local Drug Concentrations

The extent of protein degradation by intestinal enzymatic attack is concentration-dependent following Michaelis–Menten kinetics. Because regional drug concentrations of orally administered proteins depend on intestinal spreading and dilution patterns (19), modulating regional drug concentrations may alter the oral absorption of proteins. Because sCT is an excellent substrate for the pancreatic serine protease trypsin, the rate of degradation of sCT in the GI lumen is dependent on the concentration of sCT in the intestinal lumen. If degradation was the controlling factor, sCT absorption would be much more affected at low sCT concentrations (i.e., the kinetics are in the first-order region of the Michaelis–Menten curve). To evaluate the intestinal dilution and spreading on oral sCT BA, slow infusion (2 ml/min) and high dilution (25 mg/20 ml/dog) treatments were evaluated in dogs in vivo (71). In IVAP studies, the slower and larger infusion volume resulted in significantly lower sCT absorption, demonstrating that intestinal dilution and spreading significantly affected the oral BA of sCT. Scott-Moncrieff et al. (82) reported increased insulin absorption after direct jejunal administration in dogs of a 30-mM sodium glycocholate and 40-mM linoleic acid mixed micelle formulation, although the apparent bioavailability was only 1.8%. This same formulation approach elicited 41% insulin bioavailability in a rat loop model, and the researchers proposed that the much-reduced effect in dogs was possibly attributable to

Fig. 11 Duodenal pH recovery (A) and sCT absorption (B) profiles when enteric capsule disintegrated at the duodenum after oral administration of an sCT formulation containing 565 mg of citric acid and 1.2 mg of sCT into the normal dogs. An enteric coated capsule was tethered to a HC with a 3-0 silk suture and given orally to normal dogs with 10 ml of water. Two baseline samples were drawn before dosing and another immediately after gastric emptying. From the time the capsules enter the small intestine (SI), blood samples were taken every 10 min. When the HC showed a drop in pH, indicating the disintegration of the test capsule, more frequent blood sampling was performed (3, 6, 9, 12, 15, 20, 30, 45, 60, 75, 90, 120, 150, and 180 min). Transit time was used to estimate the SI location being monitored. Capsule disintegration in the duodenum begins 5 min after gastric emptying (GE) at 65 min. The initially variable pH momentarily reached pH 3 and soon rose above pH 5. (Reproduced from Ref. 88.)

dilution and spreading of the formulation, resulting in a reduced concentration of insulin, which increased exposure of insulin to proteolytic enzymes.

Regiospecific Targeting

The regiospecific difference of intrinsic permeability of proteins and proteolytic enzymatic activity is well documented (18). Insulin absorption was greater in the ileum and large intestine than in the jejunum using an in situ loop method (83). Several studies have indicated reduced enzymatic activity in the distal intestine (72). It has been hypothesized that the colon could be an optimal site for the absorption of peptides and proteins from the GI tract. This hypothesis is based on the fact that the colon contains little or no digestive enzymes, therefore, the inherent stability of polypeptide materials should be higher. Although the distal small intestine has less luminal and apical proteolytic activity, it has high activities of some apical peptidases (84). Colonic contents showed high degradation of insulin and calcitonin with high chymotrypsin activity, which suggests that care should be

Fig. 12 Late jejunal/or ileal pH recovery (A) and sCT absorption (B) profiles when enteric capsule disintegrated at late jejunum after oral administration of an sCT formulation containing 565 mg of citric acid and 1.2 mg of sCT into the normal dogs. This figure shows a 40-min delay between GE (less than 5 min) and disintegration. The observed pH drop was sharper and steadier, with the pH remaining below 5 for nearly 90 min. The better absorption profile occurs when disintegration begins in the lower small intestine (LSI). (Reproduced from Ref. 88.)

taken when administering protein drugs to the large intestine for colon-specific drug delivery (75).

Recently, our group published baseline PK information on the regional dependence of unformulated sCT oral absorption evaluated by direct administration into the PO, ID, IL, and IC by means of surgically implanted, chronic catheters (71) (Fig. 6). The plasma concentration and bioavailability values of sCT in dogs are shown and compared with p.v. and s.c. routes in Fig. 10. Plasma sCT concentrations after a p.o. dose were below the LOQ (80 pg/ml), and this may be attributed to the extensive gastric and/or intestinal enzymatic degradation. Absorption of sCT after ID administration was rapid, with peak concentrations occurring within approximately 10 min. BA of sCT was $0.039 \pm 0.017\%$, $0.064 \pm 0.022\%$, and $0.021 \pm 0.004\%$ for ID, IL, and IC administration, respectively, in IVAP dogs. Compared with that in other regions, the low BA of sCT in the colon is probably related to the combined effects of poor membrane permeability and/or proteolytic degradation by microorganisms specifically residing in the colon. The colonic results in dogs suggest that additional formulation efforts may be required to successfully deliver sCT to the colon. Calcitonin was rapidly degraded in cecal supernatants by microorganisms (85). Interestingly, the rational design of colon-specific protein/peptide delivery systems has been based on two premises: 1) that the colon compartment has decreased pancreatic proteolytic activity, and/or 2) the colon

possesses bacterial activities with unique specificities for polymer targeting (86, 87).

The successful oral delivery of sCT also depends on intestinal spreading and dilution patterns (19). As a consequence, modulating regional sCT concentrations and/or pH using a formulation approach may alter the oral absorption of CT. To understand the oral absorption process, there is a need to define both the location of release of the delivery system's contents and its effective transit time through the gut. Recently, our group published results using a radiotelemetric measurement of intestinal pH, radiographic visualization of intestinal tract, and pharmacokinetics to investigate how upper small intestine (USI) and lower small intestine (LSI) react differently in intestinal spreading and pH recovery in conscious IVAP beagle dogs (88). Regional intestinal differences of spreading and pH recovery were studied. One port was placed in the duodenum and a second port in the ileum. Fluoroscopy and Heidelberg studies were performed to characterize the intestinal spreading and pH recovery. A radiopaque dye and CA were infused into the ports, and a radiopaque powder capsule containing CA was given orally. Fluoroscopy clearly showed that when the radiopaque dye was infused into the duodenum and capsule disintegration occurred early, there was significant dilution and spreading of the excipients throughout a large section of upper small intestine. Once mixed, the contents moved slowly down the GI tract. However, when the radiopaque dye was infused into the ileum and capsule disintegration occurred lower down, the excipients moved along as a bolus (i.e., a plug). Hence, the local exposure of the intestinal wall was more concentrated in the lower small intestine. The results of the pH monitoring concurred with those of the fluoroscopy studies. In the duodenum, the pH dropped only momentarily then rose quickly. However, steady pH lowering and slower recovery were recorded in the lower small intestine. To investigate the regional intestinal differences of spreading and pH recovery and their impact on sCT oral absorption, normal male beagle dogs were dosed with an enteric capsule containing 565 mg of CA and 1.2 mg of sCT (88). Regular blood samples were collected and analyzed using RIA to determine the absorption characteristics of sCT. Figs. 11 and 12 show two extreme cases demonstrating how the same formulation can produce different results depending on where it begins to disintegrate. Because sCT is protected by low pH conditions (78) and is readily absorbed when concentrations are high, the best absorption occurs when disintegration begins lower in the small intestine. Fig. 11 depicts the disintegration of the delivery system in the duodenum, beginning 5 min after GE (65 min). The initially variable pH momentarily reaches pH 3 and soon

risers above pH 5. Fig. 12 shows a 40-min delay between GE (less than 5 min) and disintegration. The pH drop was sharper and more steady. The pH remained below 5 for nearly 90 min. The C_{\max} and AUC were 1.3 ng/ml and 47 ng·min/ml, respectively, for duodenal disintegration (Fig. 11), whereas the values were 4.1 ng/ml and 234 ng·min/ml, respectively, for late jejunal/or ileal disintegration (Fig. 12). These results show the regiospecific intestinal absorption of sCT and how it relates to the effective transit time (i.e., disintegration time after GE) of the delivery system in the small intestine. Plasma levels of sCT were optimal when disintegration occurred in the mid to lower SI.

Chemical Modification

Peptide and proteins often possess physical and/or chemical properties that present significant stability problems not encountered with many small, organic drug molecules. Because of the complex nature of proteins, self-aggregation is always a concern in formulation efforts. The tendency of insulin to form hexamers is well documented, and the absorption of hexamers will most likely be very different from monomer absorption. Hovgaard et al. (89) reported the use of alkyl saccharide surfactants (e.g., dodecyl maltoside) to minimize insulin aggregate. The insulin–dodecyl maltoside complex also afforded some protection against enzymatic degradation. Human calcitonin is also known to self-organize into fibrillar structures with reduced biologic activity (90). The use of various surfactant approaches to maximize monomer concentration during protein release may afford advantages in minimizing the size of the complex that must cross epithelial cell layers. Another potential oral delivery approach is the chemical modification of proteins to produce prodrugs and analogs. It is plausible that this approach may protect protein against degradation by proteases and other enzymes present at the mucosal barrier and renders protein more lipophilic, resulting in increased BA. Using chemical modification with fatty acids (20, 21) or *N*-acylated α -amino acids (22), a significant increase in CT intestinal absorption was observed in comparison with the native CT. The stability and permeability of peptides were improved by acylation with fatty acids and the derivatized amino acids only weakly inhibited by trypsin or leucine aminopeptidase. The stability of peptides in gastrointestinal fluids and serum was improved by substituting D-amino acids (23, 24). As exemplified by cyclosporine, the cyclic 11-amino acid compound has a surprisingly high bioavailability by chemical modification to improve its stability within the GI tract and to make it more lipophilic to enhance membrane permeability. When

administered in the microemulsion formulation, 50% or more of this molecule can be absorbed from the GI tract (11, 12, 91). Chemical modification of small peptides has been successful in protecting certain peptide structures from enzymatic attack without significant loss of biological activity, but less success has been achieved with larger polypeptides.

CONCLUDING REMARKS

Establishing an oral delivery system for peptides and protein drugs is of great importance because parenteral administration results in poor patient compliance during chronic treatment, resulting in limited clinical utility. The advantages of oral delivery systems in terms of patient compliance and acceptability are further augmented by the potential cost savings because noninvasive delivery routes do not require sterile manufacturing, and administration can be effected without direct involvement of a healthcare provider. The clinical development of protein pharmaceuticals, however, has been impeded because of poor absorption across biological membranes and rapid proteolytic degradation that typically result in low bioavailabilities. Although only very limited success (e.g., cyclosporine) has been achieved in developing and marketing oral peptide delivery systems, interest remains extremely high. It is clear that a well controlled and rational formulation design process is necessary. The problems with protein delivery are not trivial and will not be overcome by trivial solutions. Because the barriers to protein absorption (permeability, enzymatic degradation, presystemic hepatic degradation, and chemical and physical stability) will likely exhibit significant protein specificity, delivery systems will have to be investigated and developed for efficacy and safety on a case-by-case basis. In this chapter, we focused on enhancing oral absorption using several approaches. Potential approaches to modulate the intestinal environment include modulating intestinal permeability, limiting the activity of intestinal enzymes, maintaining high local drug concentrations, and regiospecific targeting. Using these strategies, sCT oral delivery systems have been fabricated and successfully tested in humans.

OTIC PREPARATIONS

William H. Slattery III

House Ear Institute, Los Angeles, California, U.S.A.

INTRODUCTION

Otic preparations are commonly used to treat diseases of the external ear and occasionally of the middle ear. Diseases of the ear include cerumen impaction, dermatitis of the external ear canal, and infectious processes. External otitis (swimmers' ear) and chronic otitis media constitute the majority of infectious diseases of the ear. This article gives an overview of otic preparations, their uses, current availability, and the area of future development.

Anatomy and Physiology of the Ear

Figure 1 is a diagram of the normal ear, which comprises the external ear canal, middle ear space, and hearing canal, or cochlea. The outer two-thirds of the external ear canal is formed by a cartilage framework. The medial or inner one-third of the external ear canal has its framework composed of bone. There is a thin layer of skin covering this bone on the medial one-third. The outer two-thirds is also covered with skin but also has a thick soft tissue lining containing the apopilosebaceous unit. External sounds travel through the external ear canal to reach the tympanic membrane. Vibration of the tympanic membrane transmits a sound wave to the three middle ear ossicles. These, in turn, send the sound wave to the inner ear (cochlea), where it is transformed into a nerve impulse. This impulse is sent to the brain, where the perception of hearing occurs.

The normal external auditory canal has several mechanisms that protect it from infections. The S-shaped anatomy of the external auditory canal provides protection from foreign bodies under normal circumstances. The tragus provides protection anteriorly, and hair from follicles found just inside the meatus prevent airborne debris from entering.

The external auditory canal skin is normally acidic, with a pH level between 4 and 5. Keratin, which consists of desquamated epithelial cells, is produced by the epithelial (skin) lining of the external ear canal; it has an isoelectric point of pH 5. Any increase above this value causes hydration of the keratin layer, increasing susceptibility to pathogenic organisms. Because as most organisms responsible for otitis externa and chronic suppurative otitis

grow best at an alkaline pH level of 7.2–7.6, the acidic pH of the external ear canal is bactericidal or bacteriostatic to many of these pathogenic organisms. The natural low pH level is therefore helpful in preventing ear infections. Anything that alters the pH balance such as swimming may increase the risk of bacterial infections.

Enzymes produced by sweat and sebaceous glands provide antimicrobial activity. Muramidase, a lysozyme excreted by the sweat glands, may be effective in lysing *Staphylococcus epidermidis* and other gram-positive organisms found on the surface of the ear canal skin. Unsaturated fatty acids, resulting from the breakdown of lipids secreted from sebaceous glands, exert antimicrobial activity against gram-negative organisms and fungi (1).

An intact tympanic membrane protects the normal sterile middle ear space from bacterial pathogens. A ruptured tympanic membrane or tympanostomy tube allows external bacteria access to the middle ear space.

Cerumen, or earwax, is produced in the outer third of the external ear canal. It consists of keratin from the epithelial lining and the enzymes and unsaturated fatty acids produced by the sweat and sebaceous glands. It exerts a protective role by forming an oily, mechanical barrier, considered bacteriostatic and fungistatic, over the skin of the external ear canal. A cerumen plug consists mainly of sheets of keratin. It also contains hair and the secretions of both the sebaceous and ceruminous glands of the external ear canal. Contained within these secretions are glycopeptides, lipids, hyaluronic acid, sialic acid, heparin sulfate, lysosomal enzymes, and immunoglobulin (2). The overall chemical composition of cerumen consists of saturated and unsaturated long-chain fatty acids, alcohols, squalene, and cholesterol (3).

Pathology and Bacteriology of Otitis

Development of new drugs and devices to treat diseases of the external ear requires an understanding of pathophysiology and knowledge about the most common organisms responsible for ear inflammation and infections.

Acute otitis external (swimmers' ear) is an inflammatory condition of the external ear canal, most commonly precipitated by local trauma, that is, Q-tips, fingernails, or

Fig. 1 Diagram of the ear.

other foreign objects that abrade the external ear canal skin. Other predisposing factors include (4):

- Maceration of the epithelial tissue in the ear canal from prolonged exposure to water or moisture;
- Plugging of sebaceous gland ducts, which lowers resistance to infection;
- Moisture absorption by the stratum corneum layer of the epithelium at humidity levels at approximately 80%;
- Elevated ambient temperature against a background of high relative humidity;
- Invasion of exogenous organisms through breaches in a damaged epithelial surface;
- An absence of cerumen; and
- The presence of an alkaline secretion.

Clinical manifestations of the preinflammatory stage of external otitis include itching of the external ear canal and congestion of the apophyseal unit. This is thought to result from the loss of lipids in the external auditory canal that, in turn, results in an increase in the aqueous content of the stratum corneum, causing intracellular edema. The acute inflammatory stage is seen with trauma induced by scratching. By this means, bacteria are allowed access to the dermis. A spectrum of clinical manifestations occurs, ranging from mild edema of the ear canal skin with a clear serous discharge to a severe form characterized by intense pain, a grossly edematous ear canal, and a purulent discharge. A chronic inflammatory stage has also been described. It is characterized by the thickening of the skin, eczematization, lichenification, and superficial skin ulceration (4).

Otomycosis is the result of a superficial fungal infection in the external ear canal. This may commonly result from an underlying bacterial infection or occur in the presence of moist cerumen. Fungi initially implant into the stratum

corneum, where they lie dormant for several days to weeks. They then grow in the superficial layer of the skin, causing inflammation. Initially, the patient usually complains of itching. In the earliest stages, mild edema may be the only clinical symptom. Later, the patient may present with a fungal mass consisting of waxy debris surrounded by a velvety gray membrane with small black spores (5).

Chronic suppurative otitis media is an inflammatory condition of the middle ear. The presence of a tympanic membrane perforation or a tympanostomy tube allows drainage into the external ear canal. Increased vascularity of the mucosa and submucosa, combined with acute and chronic inflammatory cells, is its hallmark. Granulation tissue, fibrosis, and osteoneogenesis are also commonly present. The granulation tissue contains neutrophils and plasma cells associated with small blood vessels and fibroblasts (6).

Pseudomonas aeruginosa and *Staphylococcus aureus* are the most common organisms responsible for acute otitis externa. *Proteus* species are thought to be responsible for the chronic inflammatory stage associated with it. *Aspergillus niger* and *Candida albicans* are the most common organisms responsible for otomycosis. *Mucormycosis*, yeast-like fungi, dermatophytes, and *Actinomyces* may also be seen (5).

Cultures from patients with chronic suppurative otitis media demonstrate that the most common responsible organisms are *P. aeruginosa* and *S. aureus*. These are usually mixed infections with a variety of organisms present (7, 8), and they exhibit a higher resistance to antibiotics.

In a study of 119 cases of chronic suppurative otitis media, Papstavros (9) noted a large number (81%) of gentamicin-resistant organisms in patients previously treated with topical gentamicin. Brook (7) cultured drainage from 54 children with chronic suppurative otitis media and showed that 70% of these patients harbored β -Lactamase-producing bacteria. Of 37 patients with β -Lactamase-producing bacteria, 21 had been treated previously with an oral penicillin or cephalosporin. No child in this study had received prior ototopical drops. In 39% of the children with bilateral-draining ears, a different organism predominated on each side. Both of these studies demonstrate the potential for encountering resistant organisms in chronic otitis media after previous oral or topical antibiotic therapy.

Cerumen Preparations

Normal desquamation of the epithelial layer of the external ear canal results in migration of cerumen toward

the meatus. Any interference with this normal self-cleaning mechanism results in cerumen impaction. An in vitro study has demonstrated that cerumenolysis occurs as the keratin cells, the major constituents of a cerumen plug, are hydrated, resulting in lysis of these cells (2). Consistent with this finding, aqueous preparations have been demonstrated to be better cerumenolytic products than organic, nonaqueous preparations (2, 10, 11). Before using any cerumenolytic agent, the presence of an intact tympanic membrane must be confirmed to prevent two possible complications. Introduction of these compounds into the middle ear is often painful, and the irrigation of cerumen with its keratin cells into the middle ear space may result in a cholesteatoma, a benign but destructive skin growth that requires surgical treatment.

Impacted cerumen can be simply removed by instillation of mineral oil or glycerin into the ear canal. These solutions soften the cerumen, facilitating the separation of the keratin plug from the epithelium, and thus assist the normal migration of cerumen toward the external meatus. Irrigation of the ear canal with hydrogen peroxide is another simple method. The release of oxygen provides a mechanical means for both softening the cerumen and separating it from canal skin. Hydrogen peroxide also increases the moisture within the ear canal, because the breakdown of hydrogen peroxide is water and oxygen. This may predispose to acute otitis externa by increasing the amount of moisture within the ear canal.

Unfortunately, these simple methods are not always successful, and cerumenolytics have been developed to help dissolve cerumen and facilitate its removal. In severe cases, flushing the ear canal with a rinsing solution or physical extraction is still required.

Over the years, numerous cerumenolytic agents composed of aqueous solutions or organic solvents have been tested (Table 1) (12). Currently, the most common over-the-counter products consist of carbamide peroxide in glycerin. The latter softens the wax, whereas the oxygen

released from the peroxide helps to loosen tissue debris. Usually, this agent has to be applied repeatedly over several days for the wax to soften. The softened wax may be removed with gentle irrigation or by blowing air into the external canal.

Triethanolamine polypeptide oleate condensate in propylene glycol (Cerumenex) requires a prescription. Its mechanism of action is thought to result from softening of the cerumen plug and lubrication of the ear canal (2), which is usually achieved in 15–20 min; however, mechanical removal of the cerumen plug may still be necessary. Application of this agent is best confined to a physician's office because severe allergic skin reactions occur occasionally.

Although not marketed as a cerumenolytic, docusate sodium has been found to be a very effective agent (13). Most commonly used as an aqueous fecal softener, its action on cerumen results in keratin cell expansion and lysis. The preparation is alkaline and in solution releases free hydroxyl ions (2). Drops placed in the ear canal for 10–15 min usually result in cerumen disimpaction. The plug may then be easily rinsed out of the ear canal or mechanically removed.

The ideal cerumenolytic preparation (a hypo-osmolar, alkaline, aqueous solution) has not yet been developed. It should be able to lyse the keratin cells of cerumen and allow for easy disimpaction (2).

In contrast to the use of cerumenolytic agents, cerumen replacement products for conditions such as dry skin, eczema, psoriasis, and chronic otitis of the external ear canal are occasionally required for some patients. Unfortunately, there is no product available currently to meet this need.

Antiseptics

Antiseptic agents are often used for the treatment of external ear canal disease. As with cerumenolytics, the

Table 1 Cerumenolytic products

Product	Cerumenolytic agent	Other ingredients
Cerumenex	Triethanolamine polypeptide oleate condensate	Propylene glycol Chlorbutanol (0.5%)
Debrox drops	Carbamide peroxide (6.5%)	Glycerin Propylene glycol Citric acid
Murine ear drops	Carbamide peroxide (6.5%)	Alcohol (6.3%) Glycerin

presence of an intact tympanic membrane must be confirmed before their use. Some antiseptics are commonly used for otologic surgical prophylaxis. Antiseptic otologic preparations are marketed only as the acetic acid solutions.

Acetic acid preparations (usually 2–5% solutions) have both antibacterial and antifungal activities. They are particularly useful against *P. aeruginosa*, *Staphylococci*, β -hemolytic *Streptococci*, *Candida* species, and *Aspergillus*. No organisms are resistant to these preparations (14). Acetic acid solutions placed in the external ear are generally well tolerated and nonsensitizing; however, instillation into the middle ear cavity is associated with pain. The primary drawback of these agents is the vinegar-like smell associated with the instillation. Acetic acid solutions may be combined with aluminum acetate or a steroid compound for anti-inflammatory and antipruritic properties (15). There is a tendency for acetic acid solutions to induce proliferation of the keratin layer, thus increasing the amount of debris within the ear canal associated with these infections. This may complicate the infection, making it slower to resolve.

General antiseptics such as povidine iodine (Betadine[®]), chlorhexidine gluconate (Hibiclens[®]), and hexachlorophene (pHisohex[®]) may be used ototopically for surgical prophylaxis. Povidine iodine is the most common preparation used because of its broad spectrum of activity against microflora, microzoa, and viruses. It must be prevented from entering the middle ear during surgical prophylaxis because it inhibits fibroblast migration during the healing process. Either chlorhexidine or hexachlorophene may be used for surgical prophylaxis in patients who are allergic to iodine. Chlorhexidine is the preferred agent in the iodine-allergic patient because it has a broad spectrum of antimicrobial activity against both gram-positive and gram-negative organisms. Hexachlorophene's bacteriostatic activity is more effective against gram-positive than gram-negative organisms, and supuration decreases its activity (15, 16).

Isopropyl alcohol is used to rinse the ear canal in patients prone to the development of external otitis. It is commonly applied after swimming as a prophylactic measure. Although isopropyl alcohol has broad bactericidal activity, it is widely used as a drying agent for the external ear canal. It displaces water left in the ear canal after swimming. Application into the middle ear space causes severe pain, and it should not be used in the presence of a perforated tympanic membrane.

Gentian violet and thimerosal (Merthiolate) are used for the treatment of fungal infections and are discussed later.

Antifungal Preparations

Most otomycotic infections are the consequence of treatment with antibiotics. Simple cleaning of the external ear canal and discontinuation of the medication will usually suffice to clear up the infection. However, primary and persistent infections require ototopical antifungal medications (Table 2).

Clotrimazole, as a 1% solution, is the most effective topical fungicide for the treatment of otomycosis. It is active against *Aspergillus* and *Candida* species, the most common pathogens responsible for these infections. It acts by interfering with the biosynthesis of ergosterol and is very effective for refractory or chronic cases caused by the dermatophytes or *Candida* species (17).

Amphotericin B is also an effective ototopical preparation. It may be used as a lotion or in a powder form (shown later). Its spectrum of activity covers a variety of fungi, including those responsible for otomycosis. Topical therapy is well tolerated with only rare minor side effects of local skin irritation reported. It is poorly absorbed through the skin (18).

Nystatin and miconazole have a spectrum of activity similar to that of amphotericin B against the common yeast and fungi responsible for otomycosis (17). Nystatin is occasionally used in solution as an ototopic drop. Miconazole is rarely used because it is readily available only as a cream. Application into the ear canal is difficult without impairing the hearing.

m-Cresyl acetate (Cresylate), a derivative of cresol, is marketed as an ototopical antifungal preparation. It is highly active against *Candida* and *Aspergillus*. The ear canal may be painted with *m*-Cresyl acetate on a cotton-tipped applicator, or the compound may be used in solution as an ototopical drop. It is considered the antiseptic of choice for the treatment of otomycosis because it is easily used in the outpatient setting, and, in contrast to gentian violet and thimerosal, no staining is associated with its use. However, eczematization may occur if applied to the concha, and therefore its application should be limited to the external ear canal (16, 19).

Gentian violet is used regularly in the office setting for the treatment of fungal infections. It also has bacteriostatic and bactericidal activity against most gram-positive organisms. The external ear canal is painted with the gentian violet on a cotton-tipped applicator under direct vision using an operating microscope. This compound is a strong dye, and blind application into the external ear canal is difficult without staining. For this reason, self-application by the patient is rarely performed (16).

Thimerosal (Merthiolate) may also be used topically for the treatment of otomycosis. Considered bacteriostat, it is

Table 2 Otomycotic preparations

Product	Antifungal agent	Other ingredients
Otic Domeboro solution	Acetic acid (2%)	Aluminum sulfate Boric acid
VoSol Otic solution	Acetic acid (2%)	Propylene glycol (3%) Benzethonium chloride
VoSol HC Otic solution	Acetic acid (2%)	Hydrocortisone (1%) Propylene glycol (3%) Benzethonium chloride
Fungizone lotion	Amphotericin B (3%) Thimerosal	Propylene glycol
Lotrimin solution	Clotrimazole	Polyethylene glycol
Mycelex solution	Clotrimazole	Polyethylene glycol
Cresylate solution	<i>m</i> -Cresyl acetate (25%)	Propylene glycol Isopropanol (25%) Ethanol (10%)
Gentian violet solution	Gentian violet (1%)	
Merthiolate	Thimerosal 1:1000	
Monistat-Derm lotion	Miconazole (2%)	Pegoxol 7 stearate Mineral oil Benzoic acid
Nystatin suspension	Nystatin (100,000 U/mL)	None

an excellent antiseptic agent in vitro against the common yeast and fungi responsible for otomycosis (16, 17).

Fungal cultures may be required in refractory or persistent cases of otomycosis, in which less common fungi may be responsible; the appropriate ototopical agent may be selected based on culture results. Systemic antifungal medications are rarely indicated for the treatment of otomycosis, unless associated with systemic fungal infections.

Topical preparations for the treatment of otomycosis should not be used in the presence of a perforated tympanic membrane.

Antimicrobial Drops

As a group, antimicrobial otic drops are the most commonly prescribed ototopical medication (Table 3). Most of the preparations listed in Table 3 contain a mixture of antibiotics in combination with a steroid agent. Acetic acid or an alcohol may be added for bactericidal activity. Some of these preparations contain acetic acid as the primary antibacterial agent. Most of these compounds have a low pH, between 3 and 5, similar to that of the normal external ear canal.

Antimicrobial otic drops should be used with caution in the presence of a tympanic membrane perforation because of the potential for ototoxicity. In the case of suppuration, the ear canal should be cleaned before drop instillation.

Purulence within the ear canal will not allow ototopical drops to penetrate the skin, and it is thus prevented from treating the ear infection. Ear cleaning is extremely important when suppuration occurs.

Neomycin and Polymyxin B are the two most common antibiotic agents found in ototopical preparations. Neomycin is bactericidal to many gram-positive and gram-negative organisms, including those responsible for external and chronic otitis such as *S. aureus*, *C. diphtheriae*, *Escherichia coli*, *Proteus*, *Enterobacter*, *Klebsiella*, and *Haemophilus influenzae*. It has no activity against anaerobes, and many strains of *Pseudomonas* are resistant. Cutaneous hypersensitivity is estimated to occur in 6–8% of patients who receive topical treatment (20).

Polymyxin B and Colistin (polymyxin E), first discovered in 1947, have similar antibiotic spectrums limited to gram-negative organisms. *P. aeruginosa* is particularly sensitive to these medications. Other sensitive gram-negative organisms include *Enterobacter*, *E. coli*, *Klebsiella*, and *Haemophilus*. These agents interact with the cell-membrane phospholipids to disrupt the bacterial cells; hypersensitivity is very rare. These antibiotics are poorly absorbed, even when applied to denuded skin (21).

Chloramphenicol may be used ototopically for selective cases of chronic otitis. Despite its relative lack of activity against *P. aeruginosa*, it is bacteriostatic against the other common organisms responsible for chronic otitis,

Table 3 Otic antimicrobial preparations

Product	Ingredients				
	Antimicrobial	Anti-inflammatory	Acid	Antiseptic	Others
Chloramphenicol Cipro HC Otic	Chloramphenicol Ciprofloxacin	Hydrocortisone (1%)	Hydrochloric acetic	Alcohol	Propylene glycol Polyvinyl alcohol Sodium acetate Phospholipon 90HB Polysorbate Thonzonium Polysorbate 80 Sodium acetate Glycerin

including *E. coli*, *Clostridium* species, *S. aureus*, *H. influenzae*, *Bacteroides fragilis*, *Klebsiella* species, and certain strains of *Proteus* (15, 22). However, blood dyscrasias and death have been reported after local application, and local skin hypersensitivity may occur with topical therapy (12). Although rarely used for primary therapy, it is used for refractory chronic otitis, especially when a susceptible organism is cultured.

Despite similar antibacterial composition, ototopical preparations may differ in delivery vehicle and pH level. Cortisporin Otic Solution is the most acidic, whereas Coly-Mycin S Otic has a pH of 5, the highest of the group (12, 23). The low pH of these compounds and the alcohol used as an antiseptic agent cause a burning sensation when in contact with the middle ear.

Otobiotic and Pyocidin-Otic contain only the antibiotic polymyxin B. These compounds are useful for the patient allergic to neomycin but should be used only in certain cases because polymyxin B does not act against gram-positive organisms such as *Staphylococcus* and the gram-negative organisms *Proteus* and *B. fragilis*.

Two new fluoroquinolone otic preparations have recently been introduced. Floxic Otic and Cipro HC have recently been approved by the FDA for treatment of external ear disease. Ciprofloxacin and ofloxacin are the active ingredients in these two preparations. Both antimicrobials have a broad spectrum of activity, especially against organisms commonly responsible for otitis externa, including *Pseudomonas*, *S. aureus*, *P. mirabilis*, *Streptococcal* species, and various gram-negative enteric *Bacilli*. In addition, Cipro HC contains hydrocortisone, which adds to the anti-inflammatory properties of this agent. Cipro HC has a low pH level, which makes it ideal for treating external otitis. Floxin Otic has a buffered pH and is FDA-approved for installation into the middle ear space. One difficulty with these newly introduced medications is that many insurance health plans do not cover the cost. These medications are ideally suited for first-line therapy.

The ototopical antimicrobial preparations stated earlier suffice for most cases of otitis externa and selected cases of chronic suppurative otitis. However, these compounds have a limited effect in certain patients with resistant strains of bacteria, drug-induced allergies, or a tympanic membrane perforation that requires administration into the middle ear space. In the last case, ototopical preparations may cause pain because of the acidic pH or the presence of alcohol. Ototoxicity of neomycin, polymyxin B, and colistin is also of concern, and many otolaryngologists prefer topical ophthalmic preparations (23). Ophthalmic preparations are discussed in the article *Ocular Drug Formulation and Delivery* in this volume.

Ophthalmic compounds that may be used as ototopical remedies are given in Table 4 (12). Generally, these products differ from the otic preparations in a neutral pH and the absence of alcohol. For example, in contrast to its otic counterpart, Chloromycetin Ophthalmic has a buffered pH and offers a preparation with hydrocortisone. Likewise, the primary difference between Cortisporin Ophthalmic and the otic preparation is the neutral pH.

Compared with the otic antimicrobial preparations, ophthalmic antimicrobial preparations offer the physician a broader range of antibiotics to treat the difficult ear infection. Gentamicin, tobramycin, and sulfonamides are the most common antibiotics used.

Gentamicin and tobramycin ophthalmic preparations are commonly used to treat difficult ear infections. The latter is less toxic than gentamicin, and its activity against *Pseudomonas* is higher. These antibacterial agents also have a wide spectrum of activity including *Proteus*, *Klebsiella*, *E. coli*, and *Staphylococcus* (20). As stated earlier, resistance to gentamicin develops after topical use (9). Although both of these drugs are known to be ototoxic, the clinical significance is thought to be minimal.

Sulfonamides are bacteriostatic against a wide range of gram-positive and gram-negative organisms. In chronic otitis, ophthalmic preparations are used for their activity against *P. aeruginosa*, *Proteus* species, *Streptococcus*, *Corynebacterium*, *Diphtheriae*, and *H. influenzae*.

Ciprofloxacin is well known for its wide range of bactericidal activity, especially against *S. aureus*, *Staphylococcus epidermidis*, and *P. aeruginosa* (24). This preparation has the ideal antimicrobial spectrum for refractory otitis; however topical therapy should not be considered alone for more serious infections such as those with underlying osteomyelitis.

The ophthalmic preparations should only be used in refractory cases of otitis because organism resistance may develop with widespread use. Ophthalmic preparations are also not improved by the FDA for use in the ear canal, but treating physicians may use their discretion for refractory cases. The recent introduction of Floxin and Cipro Otic drops have decreased the use of ophthalmic preparations for the treatment of refractory ear canal conditions.

Powder Preparations

Powdered preparations have been used for many years in otology. These were originally applied as dusting powders for chronic otitis and were especially useful for a mastoid cavity. Before the advent of antibiotics, antiseptic and acid powders were insufflated into mastoid cavities. Unlike many other otic preparations, powders do not cause pain on administration.

Table 4 Ophthalmologic antimicrobial preparations commonly used ototopically

Product	Ingredients				
	Antimicrobial	Anti-Inflammatory	Acid	Antiseptic	Others
Chloromycetin ophthalmic solution	Chloramphenicol		Boric		Buffer
Chloromycetin hydrocortisone	Chloramphenicol	Hydrocortisone (2.5%)	Boric		Buffer Chloesterol Methylcellulose Benzethonium chloride ^a Benzethonium chloride ^a Sodium acetate Mannitol Edetate disodium Mineral oil Propylene glycol Polyoxyl 40 sterate Glyceryl monostearate Phenylmercuric nitrate Disodium phosphate Monosodium phosphate Benzalkonium chloride ^a Sodium phosphate Tyloxapol Edetate disodium Benzalkonium chloride ^a Propylene glycol Polyoxyethylene-polyoxypropylene compound
Ciloxan	Ciprofloxacin		Acetic Hydrochloric ^b		
Cortisporin ophthalmic solution	Polymyxin B Neomycin	Hydrocortisone (1%)	Sulfuric ^b	Cetyl alcohol

Sulfanilamide	50
Fungizone	5
Hydrocortisone	1

^aFor patients who are allergic to sulfanilamide, these preparations are available without sulfanilamide.

A powder insufflator can be used for the instillation of antimicrobial agents into the external ear canal or mastoid cavity (25). Current antibiotic preparations suitable for the insufflator device are shown in Table 5 (26). They are packaged into capsules that fit into the insufflator. The patient can easily blow the powder into the ear canal without spreading it around. The activity of these antibiotics against organisms responsible for chronic otitis has already been stated. Other common antibiotics or antiseptics may be applied in powder form in an otolaryngologist's office; boric acid is the most common example (Fig. 2).

Anesthetic Preparations

Anesthetic agents (Table 6) are used to eliminate the pain associated with infections such as external otitis, otitis media, and bullous myringitis. They may also be used locally before surgical manipulation, most commonly during myringotomy. These agents are only recommended for patients with an intact tympanic membrane.

Fig. 2 Bulb insufflator used for antibiotic powders. The capsules contain the antibiotic powder and are placed inside the bulb insufflator.

Most local anesthetic preparations contain benzocaine. Because benzocaine is poorly absorbed through the skin, it remains localized for a long time; however, its effectiveness is unpredictable. Benzocaine has also been known to produce local hypersensitivity reactions (15).

EMLA is a new anesthetic ointment that anesthetizes the external ear canal and eardrum. After keeping the ointment in the external ear canal for 15–20 min it is removed. The surgical procedure may then be completed. This product has been used for myringotomy under local anesthesia.

Phenol is the common topical anesthetic for myringotomies. It is applied over the specific area of the tympanic membrane where the myringotomy is to be performed. It

Table 6 Otic anesthetic preparations

Product	Anesthetic agent	Other ingredients
Americaine Otic	Benzocaine (20%)	Glycerin Polyethylene glycol Benzethonium chloride
Auralgan Otic solution	Benzocaine Antipyrine	Glycerin
EMLA	Lidocaine Prilocaine	Polyoxyethylene Carboxypolyethylene Sodium hydroxide
Phenol	Carbolic acid	

acts by causing instant epidermal destruction. The section of the tympanic membrane in contact with the phenol turns white owing to the anticipated proteins, indicating an anesthetic effect. Healing occurs by hyperplasia of the epithelium and connective tissue but may take some time after applications (16).

Other Preparations

Propylene glycol is a good base for many of the combination antibiotic drops. It acts as a dehydrating agent to fungi and enhances the effectiveness of other antifungal medications. Occasionally, a patient may develop a contact dermatitis from this agent.

Corticosteroids are added to many ototopical combination drops to reduce the inflammation and puritis associated with the acutely infected ear. Corticosteroids may also be used primarily to treat dermatoses found in the external ear canal, primarily psoriasis and seborrheic dermatitis. These compounds may reduce the scaling, itching, and inflammation.

Silver nitrate, as a solution or as a powder on a stick applicator, is occasionally used in the external ear canal as a cauterizing agent. It may be applied to granulation tissue or to the site of a superficial infection. Generally, it is well tolerated; however, if it is excessively applied and bone is exposed, the area does not heal, and surgical correction may be required.

Ototoxicity

The subject of ototoxicity must be addressed whenever discussing the development of new ototopical preparations. It is an important topic from a clinical standpoint and a medicolegal point of view.

In the presence of an intact tympanic membrane, ototoxicity is less important, because the preparation has to be systemically absorbed for an ototoxic effect to occur. This issue is most relevant in cases of chronic suppurative otitis media with a perforated tympanic membrane for

which the ototopical medication has the potential to reach the inner ear via the middle ear. Placed within the middle ear, ototopical medication may diffuse across the oval or round window, resulting in inner ear absorption. These windows consist of a thin membrane separating the middle ear space from the inner ear fluids. There is controversy regarding the clinical relevance of ototoxicity in cases of chronic suppurative otitis media.

A comprehensive review of the ototoxicity of the various ototopical preparations has been published (28). Table 7 lists the agents in which ototoxicity has been demonstrated in animal models. There is no antiseptic that is thought to be free of ototoxicity. The antifungal medications nystatin, amphotericin B, clotrimazole, and tolnaftate have been tested in animal models and found to be free of ototoxicity. The antibiotic found in common otic compounds (Polymyxin B and Neomycin) has demonstrated ototoxicity. Chloramphenicol and Colistin are also ototoxic. The new quinolone otic preparations (Floxin and Cipro) have not demonstrated ototoxicity. The antibiotic Sulfacetamide present in ophthalmic preparations has not demonstrated ototoxicity. No evaluation of the ototoxic effects of topical Tobramycin has been published, although it is thought to be similar to gentamicin in this respect. Although hydrocortisone has demonstrated ototoxicity in animal models, other corticosteroids such as triamcinolone and dexamethasone have not. Desonide has not been tested.

Numerous animal studies have been undertaken to evaluate the ototoxic effects of these different medications; however, the results must be examined with caution because of the differences between the animal models and the human temporal bone. The small mammals used in these studies, usually chinchillas or guinea pigs, have a round window that is easily exposed and very thin compared with the human ear. The human round window is more deeply recessed in bone and is six times thicker than that in the chinchilla. Some temporal bones may actually demonstrate a thin shelf of bone or a thick fibrous plug covering the round window. (29) Further studies must be completed to determine the significance of these

Table 7 Ototoxic otic preparations

Solvent	Antifungal	Antiseptics	Antimicrobials	Anti-Inflammatory

differences with respect to ototoxicity and ototopical preparations.

A 1992 survey of otolaryngologists revealed that 80% believed that the risk of sensorineural hearing loss resulting from otitis media was higher than the risk of sensorineural hearing loss from using an ototopical agent known to be ototoxic (30). As McCabe noted in his editorial comment (31):

In 30 years of practice, I have not recognized a single ear damaged in hearing from any antibiotic ear drop, however long term. This total experience has not changed since then.

This comment is important not only for patient care, but also for medicolegal reasons.

SUMMARY

A variety of otic preparations have been reviewed here, including indications, side effects, and limitations. The ideal cerumenolytic compound has not yet been developed, nor has a cerumen replacement product. Antiseptics enjoy wide application but are limited when used in the presence of a perforated tympanic membrane. Available antifungal medications appear to be adequate for the treatment of otomycosis, although none have been approved as otic preparations. The limitations of the otic antimicrobial drops have been stated, including the potential both for organism resistance and for ototoxicity. The recent introduction of Floxin and Cipro HC products make available better otic antimicrobial drops for treatment of otitis externa and chronic otitis media. These drops have generated renewed interest in the development of ototopical preparations. Powder preparations are not widely available and must be specifically prepared by a pharmacist each time they are dispensed.

The current practice of some otolaryngologists using medications that have not been approved by the FDA for ototopical use demonstrates the need for new otic preparations. It is hoped that this article will lay the foundation that to enable the development of these new products.

OUTSOURCING OF PHARMACEUTICALS

Duane B. Lakings

*Drug Safety Evaluation Consulting, Inc.,
Birmingham, Alabama, U.S.A.*

INTRODUCTION

Outsourcing of pharmaceutical development is big business and getting bigger. Of the over \$40 billion per year research and development budget of pharmaceutical companies, about one-fifth, or \$8 billion, is presently expended at contract service organizations (CSO), and the amount is projected to increase at a rate of about 10% per year in the future. The term CSO includes contract research organizations (CRO), contract manufacturing organizations (CMO), site management organizations (SMO), and any other organization that provides the pharmaceutical industry, or client, with a contract service. Most of this outsourced effort is being expended on the nonclinical drug development, clinical trials, and manufacturing aspects of the drug development process. However, many clients are now using CSOs for drug discovery and potential for development characterization support to generate novel compounds with biological activity against a given target system and then to identify those discovery leads that have the desired attributes with a minimum of detrimental effects needed to become successful preclinical drug candidates. The purposes of this article are to:

1. Describe the history and present status of CSOs;
2. Discuss how clients and CSOs interact;
3. Summarize the services CSOs provide clients;
4. Outline how virtual organizations and consultants interface with clients and CSOs; and
5. Present emerging trends for CSOs.

A complete listing of all the CSOs that offer clients support in one or more of the drug discovery and development processes is beyond the scope of this article. A number of reports are available that provide detailed information on CSOs and the services they provide. Some of these reports are listed in the References. Another common source of information on the services offered by CSOs is the Internet, where most CSOs maintain detailed, up-to-date websites.

HISTORY OF OUTSOURCING

CSOs have been around since the 1940s but have only been major participants in the drug development process for the past 30 years or so and in drug discovery for 10 years or less. The first firms to offer drug development services were not-for-profit research institutes such as Stanford Research Institute, now SRI International, and Midwest Research Institute. With the regulatory requirement that nonclinical safety studies, primarily in toxicology, be conducted according to Good Laboratory Practices (GLP) regulations, for-profit CSOs started to offer chronic toxicity and carcinogenicity study support. At about the same time, the clinical testing requirements needed to characterize the safety and efficacy of a novel chemical entity (NCE) increased dramatically, and Good Clinical Practices (GCP) regulations were issued. Monitoring and auditing of clinical trials to ensure that the data captured on Case Report Forms (CRFs) and other documents accurately reflected information in the raw data were initially accomplished by Clinical Research Associates (CRAs) of the clinical trial sponsor. First independent CRAs and then CSOs were employed by pharmaceutical firms to provide independent auditing of the clinical trial investigational sites.

In the 1980s, a new player came onto the field, biotechnology, with the intent to make macromolecules into therapeutic products. Although many of the new firms had excellent biology and pharmacology expertise, they knew little about the regulatory-driven nonclinical and clinical research and manufacturing requirements necessary to develop a discovery idea into a therapeutic product. Thus, these new companies turned to CSOs. However, most, if not all, of these service providers also did not know how to effectively characterize and develop macromolecules. Thus, the biotechnology companies, the regulatory agencies, and the CSOs rapidly learned how to solve the major problems associated with macromolecule research. After submitting an IND, the biotechnology companies turned to CSOs for assistance in conducting

clinical trials, which required the CSOs to expand services to include protocol development, CRF design, investigator and site selection, data management and statistical evaluation, and report writing. With the increased level of outsourcing, the number of clinical CSOs grew rapidly.

In the 1990s, a group of major events again changed the CSO playing field. The ability to generate libraries of compounds using combinatorial chemistry techniques, high-throughput screening (HTS) techniques to rapidly evaluate the biological activity of these libraries, and bioinformatics to manage and evaluate the large amount of data being generated changed the drug discovery process. The mapping of the human genome will produce a dramatic increase in the number of therapeutic targets available, with the number projected to grow from the few hundreds of targets available today to many thousands in the next few years. Drug discovery groups have been charged to expeditiously find new drug candidates to fill the drug development pipeline. Some companies have developed, or are developing, in-house groups to meet this challenge, whereas others formed partnerships with small biotechnology firms, and still others combined these approaches. In addition, a number of new CSOs were started to provide research services in these relatively novel areas of genomics, proteomics, combinatorial chemistry, HTS, and bioinformatics.

PRESENT STATUS OF OUTSOURCING

CSOs are rapidly adapting to meet the needs of their clients. These changes appear to take one of two avenues. Some CSOs, such as MDS and Quintiles Transnational, are attempting to become full-service, or almost full-service, CSOs by providing research services in drug discovery, potential for development characterization, nonclinical drug development, clinical trial research, and manufacturing. Other CSOs specialize in a given area, such as animal pharmacology studies or phase II to IV clinical trial support. Many pharmaceutical industry observers think that the midsize CSOs will disappear over the next few years, either through mergers with other CSOs or by acquisition by larger CSOs or companies that desire to enter this rapidly growing, but highly competitive, business.

Only a few years ago, drug discovery research was never, or only very infrequently, outsourced to CSOs. Grants to university groups were used to develop models and at times to test discovery leads in these newly defined models. Now, many pharmaceutical companies use CSOs in addition to university groups to support some aspects of

their drug discovery efforts. The transition from drug discovery to drug development has also undergone substantial change in the last decade. A number of CSOs now support this rapidly growing area to assist clients in determining whether a discovery lead(s) has the necessary attributes for further development. The greatest consolidation in the CSO industry has been in nonclinical and clinical drug development, in which contractors that had offered services in one of these areas are adding the other so that they can better serve clients. These additions are frequently accomplished by acquisition of other CSOs that are already offering the desired services, but some CSOs are developing and increasing their own capabilities. A similar trend is occurring in CSOs offering manufacturing support, in which capabilities to produce Good Manufacturing Practice (GMP)-quality drug substances and drug products are being augmented with services such as shelf-life stability studies and impurity profiling.

With consolidation and expansion, large CSOs are becoming bigger and are now being called mega-CSOs. Since 1996, the eight largest CSOs have made more than 40 acquisitions, suggesting that the market is shifting from small CSOs to larger firms. Some recent highly publicized acquisitions include Quintiles' purchase of Innovex and Medical Action Communications and Bulter Clinical Recruitment Service. For Phoenix International Life Sciences, which was acquired by MDS in 2000 and is now called MDS Pharm Services, expansion started in 1995 with the acquisition of I.T.E.M. Holding S.A., IBRD-Rostrum Global, Institute for Pharmacodynamic Research, Anawa Holding, McKnight, and Clinserve to provide multinational capability in clinical research and Chrysalis International to supplement services in nonclinical development. PPD, Inc. has purchased Wisconsin Analytical and Research Service, Gabbay Group, Ltd., Applied Bioscience International, Inc., Belmont Research, SARCO, Inc., GSX Technology, and ATP. Numerous other mergers and acquisitions have taken place, and the trend is expected to continue. However, for each CSO that combines with or is acquired by another CSO, a new player, usually offering a novel service such as genomics or in vitro metabolism, comes onto the field. Whether to use a mega-CSO or a number of smaller, but specialized, CSOs to support outsourcing needs is a question to be addressed by pharmaceutical clients. Another way of asking the question is whether "one-stop" shopping is better than looking at a number of "specialty houses" that offer only a limited line.

As pharmaceutical clients develop drug candidates for the global market, CSOs have expanded their services, primarily clinical trial support services, to include not only

North America, Europe, and Japan, but also a number of emerging markets. A major reason that pharmaceutical companies can enter the foreign markets and that CSOs can offer support services in these markets is the harmonization of the drug development processes through the efforts of the International Conference on Harmonisation (ICH) and the ICH guidelines. Even though ICH guidelines currently apply only to U.S., European, and Japanese research efforts, most other countries are adopting these guidelines. The presently issued ICH guidelines primarily deal with the quality of drug substances and drug products, nonclinical safety, and clinical trials. CSOs, although not a major participant in the definition of the ICH guidelines, are an influential group for their implementation.

CLIENT AND CONTRACTOR INTERACTIONS

Outsourcing is now a common practice of almost all pharmaceutical companies. For example, the use of CSOs to support some aspect of clinical trial research has grown from approximately 30% of the clinical studies conducted in 1993 to over 60% in 1997. The processes that a client uses to select a CSO and how a client interacts with the CSO ensure contracted research studies are monitored appropriately and completed on time and within budget.

A pharmaceutical company identifies a lead candidate that mediates a human disease. For a variety of reasons, corporate management decides to have some or all regulated nonclinical and clinical studies or the manufacturing aspects of drug development performed by a CSO(s). The drug development project team is commonly responsible for coordinating the outsourcing program and for ensuring that the development program stays on time, on track, and on budget. For a small company, this may be the responsibility of two or three researchers who need to have a good understanding of each of the scientific disciplines for which outsourced studies are being considered. A common practice for many firms is to use a consultant or a consulting firm to assist in outsourcing.

The first requirement for a successful research program at CSOs is to identify which aspects of the drug development program are to be conducted at a CSO and the projected timeline for when these studies need to be initiated and completed so that the results are available for decision making and regulatory agency submissions. A well constructed drug development logic plan provides much of this information. The client needs

to identify and then select the appropriate CSO(s) to conduct the desired research studies. The client also needs to monitor the CSO(s) to ensure that the studies are conducted as described in the study protocol and that the results generated are appropriately recorded first in the study records and then in a study report.

CSO Selection

The steps a client should take to identify and select CSOs include but are not be limited to:

- Preparing detailed study designs for each of the research projects to be contracted
- Determining which CSOs are to be considered
- Soliciting cost and time proposals for each study design from each CSO selected
- Evaluating the proposals and selecting those CSOs to be considered further
- Conducting site visits to ensure that the CSOs are qualified to conduct the research studies
- Negotiating time and cost for completion of the research studies
- Selecting the CSOs and awarding the contracts for each study to be outsourced.

The number of person-hours required for the identification and selection process depends on the size of the research program to be contracted. Normally, a minimum of 1 to 2 person-weeks is necessary to effectively evaluate three to four CSOs for each research study to be outsourced. Many clients use consultants to assist in the CSO selection process. However, these clients need to ensure that the consultant has the necessary expertise and knowledge of how CSOs operate. A common mistake is to hire a consultant with expertise in a disease area but not in the research process, such as toxicology or drug metabolism, or in regulatory compliance but not in the science necessary to characterize a drug candidate successfully.

Clients commonly use one of three strategies to identify CSOs. These strategies can be designated virtual, preselected, and special study. The virtual strategy is favored by clients who do not have the resources to conduct GLP-, GCP-, or GMP-regulated research studies. A primary benefit is that the various types of expertise and the infrastructure needed to support regulated studies can be devoted to completing research studies without the client having to build the in-house groups and facilities and thus experiencing costly time delays. A primary limitation is that the client can be vulnerable to poor CSO selection or to mismanagement by the CSO. In the

preselected strategy, a limited number of CSOs are prequalified to support a client's possible outsourcing needs. The qualification process usually includes a detailed site visit to determine which types of research studies can be placed at the CSO. This strategy can provide a synergistic working relationship between the client and the CSO. A major drawback is the unnecessary limitation of outsourcing. If a number of CSOs have the desired expertise but the client's prequalified list contains only a couple of those CSOs, other possibly better qualified CSOs are not even considered. The final strategy, special study, is used by some clients to place single or a few research studies with a contractor. This strategy allows a critical study to be completed to meet the timeline on a drug development plan. However, some companies use this strategy for all of their outsourcing needs and then attempt to integrate the results for the independently conducted studies into a drug development story. For a client with substantial drug development expertise, this strategy may work but requires considerable effort in identifying and selecting CSOs, monitoring the various CSOs, and synthesizing the results from the various research studies. CSOs are generally not in favor of this strategy because they become only "a pair of hands," and have little understanding of the overall development program and thus cannot provide the client with their considerable expertise. Whichever selection strategy is used, the client needs to select the CSO carefully. One poorly conducted study can effectively delay the drug development process until the study has been repeated and the results integrated into the overall story. If this delay is for a research study on the drug development critical path, the projected time for regulatory agency submission has to be changed, thus delaying approval for marketing and resulting in lost revenue for the client.

What are some of the items clients look for when evaluating and selecting CSOs? That list could be quite long, and only a few of the many criteria are presented here.

- *Project management skills:* The CSO project manager ensures that the contracted activities are completed in a timely and cost-effective manner. This individual needs to be identified early so that an acceptable working arrangement can be established.
- *Research area and therapeutic experience:* A CSO with expertise in a variety of scientific disciplines and therapeutic areas will have a pool of experts available as a knowledge resource as results become available for evaluation.
- *Flexibility and adaptability:* The ability to adapt to changes in research study parameters and timelines is

important to understanding the dynamic nature of the drug discovery and development process. A CSO needs to be able to interact effectively with a client to modify a study design or an ongoing research study.

- *Timeliness:* A CSO needs to be able to provide the contract service(s) agreed on in the desired time frame.
- *Integrity:* The results to be generated need to be accurate, complete, and unbiased. Previous performance or references from other clients can assist in ascertaining how the CSO will perform in providing "good" as well as "bad" news.
- *Quality assurance (QA) awareness:* The CSO's established procedures ensure both quality work and that current regulations are followed. A review of the CSO's standard operating procedure (SOP) manual and discussions with the QA manager will provide this information. Also, results from recently conducted regulatory agency audits should be reviewed.
- *Training:* The documented training process ensures that all research study personnel have the necessary skills for conducting their aspect of the contracted study.
- *Services offered:* The CSO offers a sufficiently broad scope of services for conducting the contracted research study in the shortest time possible. The services offered anticipate contract project demands and respond quickly to project dynamics.
- *Communication:* The CSO provides information in an acceptable format and on a timely basis. A constant open line of communication should exist between the client and the CSO.
- *Partnership:* The CSO considers itself a partner with the client and is service-oriented. The CSO creates a team environment to perform as an extension of the client's project team.

One item not listed above is cost. Most clients use cost as an evaluation criteria, at times the only criteria. Although important, cost needs to be evaluated in conjunction with other CSO selection items. A CSO offering the lowest price may not:

- Fully understand the research objectives;
- Be able to conduct the studies on the timeline desired;
- Include all the tests or evaluations necessary to support a regulatory submission; or
- Provide a complete evaluation of the study results.

If all other selection criteria among CSOs are equal, then cost can and should be used to select the contractor. Once a CSO has been selected, time and cost negotiating is justifiable to ensure that the client receives the best quality study for the best price.

CSO Monitoring

The identification and selection process is only the first step. The second aspect involves monitoring the CSOs to ensure that the research studies are conducted according to the research protocol, that the results are obtained using appropriate techniques and procedures, and that the data generated are correctly recorded and documented in the study report. Many clients hire firms, such as other CSOs or consultants, to monitor outsourced research studies, particularly clinical trials and manufacturing projects. In doing so, the clients should use the same techniques to select and evaluate the monitors as they use to identify a CSO. Monitoring studies at CSOs should include but are not be limited to:

- Reviewing and approving the protocols, which should provide information on all aspects of the study, and detailing the procedures to be followed to successfully complete the study
- Monitoring various aspects of each study to ensure that the data collected do not contain “surprises” that can prevent the results from being used to support submissions to regulatory agencies
- Assisting in the evaluation and interpretation of results to ensure that the data are analytically acceptable and correctly correlated to tell the story of the experimental results
- Reviewing study reports to ensure that they accurately reflect the generated results, document any deviation from the study protocols, and give appropriate conclusions.

The number of person-hours required to appropriately monitor a research study conducted by a CSO again depends on the size of the research program. Normally, a minimum of 1 person-week for each in-life or inpatient phase month of a research study is required and includes the time necessary to review and approve the study report.

OUTSOURCING OF DRUG DISCOVERY

Drug discovery strives to find new ways to discover novel compounds and to identify new targets for treating the various disorders affecting humans. After years of first synthesizing individual compounds, then purifying and obtaining physical and chemical characterization of the new chemicals, and finally testing the NCEs in pharmacological models of a particular human disease, the pharmaceutical industry has embraced combinatorial chemistry as a way to generate large numbers of structurally unique compounds, HTS to test these

chemicals for biological activity against a target, genomics to identify the genetic code for enzymes and proteins that might be new drug targets, proteomics to produce the newly identified natural proteins and to characterize their functions in the body, and bioinformatics to organize and evaluate the enormous amounts of data generated. Once a lead or, more likely, a group of leads is identified, the biological activity in other in vitro and in vivo pharmacology models is explored further, and structural activity relationship (SAR) techniques are used to further modify the molecular structures of the leads to identify NCEs with very high potency and specificity, which means the leads have minimal or acceptable adverse effects or interference with other physiological functions or organ systems.

The present cost and time estimate for the drug discovery and development process is approximately \$500 million and 12 to 14 years, respectively, for each new therapeutic agent that reaches the market. The time and cost profile is shown in Fig. 1. The drug discovery and preclinical phases, or the first few years, are relatively inexpensive relative to the clinical, nonclinical, and manufacturing phases, in which over 80% of the cost and more than half the time are expended. The \$500 million cost includes the money spent on the losers, those compounds that were identified as having biological activity against a target but that do not successfully complete the process. Because only approximately 2% of discovery leads selected for preclinical development enter into clinical studies and only an estimated 5% of these

Fig. 1 Time and cost profile for drug discovery and development.

drug candidates result in New Drug Application (NDA) submissions (for an overall success rate of about 0.1%), finding and gleaning the losers probably uses more than 80% of the cost and half the time needed to put a novel therapeutic agent on the market. By identifying the losers early in the process and thereby reserving precious resources for discovering compounds that have a better chance of success, companies could substantially reduce the overall cost for each new therapeutic agent and use precious resources on discovering and developing compounds with a higher probability of being a winner and thus also shorten the time required for drug discovery and development.

All successful pharmaceutical firms understand this problem and are constantly searching for novel approaches to expedite the process and to reduce the cost. One approach used more and more is to outsource some or all of the drug discovery and pharmacology aspects to CSOs that have particular expertise that are not available in a pharmaceutical company and that would be costly in time and resources to establish. This section summarizes the present scientific disciplines involved in the drug discovery process. Because the techniques and procedures used in this rapidly evolving area are changing so quickly, only summary information can be presented. A few CSOs that provide services in more than one discovery area are listed in Table 1.

The entire human genome is projected to be sequenced by 2002 or shortly thereafter. The human genome contains 60,000 to 80,000 genes that code for proteins, many of which could be new targets of mediating human diseases, and many others that have little potential as targets for drug therapy. Present projections suggest that 5000 to 10,000 of the genes, or approximately 10%, may be involved in regulating some aspect of cellular function or in producing signals to simulate or inhibit extracellular events or other cells. In combination with chemical libraries and HTS techniques, these new targets are expected to identify many novel ways of treating diseases. A major problem is determining which of these genes are important in a disease process and which are not. Proteomics is the science that will help in these determinations. The newly discovered genes can be transfected into bacterial or mammalian cell lines to produce sufficient quantities of the protein for further characterization and study.

Combinatorial chemistry technology and the merging of automated library synthesis with the traditional medicinal chemistry principles to provide a more rational approach to library generation are providing pharmaceutical companies with millions of novel compounds. Advantages of generating these diverse libraries include acting as a synthetic substitute for natural samples in random discovery screening programs and providing a

systematic approach for SAR studies to assist chemists and pharmacologists in defining the pharmacophore and other chemical structure attributes that can be important for metabolic stability, aqueous solubility, and lipid membrane penetration. A key aspect is molecular modeling, which is critical to understanding the chemical reactions and can be used to model structures, provide conformational analysis, and develop the pharmacophore or other structural attributes. To support these efforts, a number of CSOs offer combinatorial chemistry services and classical synthetic capabilities for small organic molecules and for macromolecules.

The library or other source of chemicals is screened for biological activity, usually employing an *in vitro* system in which a known biochemical process is agonized or antagonized. The identification and characterization of the target system can be a rate-limited step, especially for a newly discovered, genomic-defined target. The increased number of compounds to be tested has required pharmacologists to devise novel techniques to rapidly screen for biological activity. With a number of new targets becoming available, many pharmaceutical companies are turning to CSOs for assistance in developing and implementing HTS assay systems to evaluate the biological activity of the novel compounds in libraries.

Bioinformatics assists in understanding information content and flow in biological systems and processes and is becoming more and more important because of the unprecedented growth in quantity and diversity of these data. Applications for bioinformatic techniques include understanding biological processes and how they may malfunction, thus having an important place in drug discovery and development processes. At present, the role and function of most proteins are at best incomplete and often nonexistent. Bioinformatics can assist researchers in understanding what protein each gene produces and in determining the physiological role and function of each of these proteins. Bioinformatics can facilitate the selection of drug targets, biological pathways, receptor functions, gene regulation, and intercellular communication and the impact that each of these has on the others and on normal and disease states. A number of CSOs have developed bioinformatics tools and techniques and offer these services to clients. Because this area is growing so rapidly and new players are continuously entering the field, any list of CSOs involved in bioinformatics would be outdated before publication.

After a biologically active compound(s) has been identified, additional, experiments are conducted to further study the pharmacological activity. These studies are frequently conducted in *in vivo* models, and analogs of the

lead are also tested to further characterize the mechanism of action and to ensure that a compound with high potency and specificity is identified. This more classic *in vivo* approach to evaluating the biological potency is a more rigorous SAR assessment than one that uses *in vitro* systems because the discovery lead(s):

- Has to be administered to the animal model and be delivered to the site of action
- Is subjected to drug metabolizing enzymes
- May cause unexpected responses that describe a novel activity or an unwanted adverse effect
- Has to prevent the normal clearance processes from eliminating the lead before it reaches the target in sufficient concentration to elicit the desired biological response.

For these and other reasons, most pharmacologists still consider the use of *in vivo* animal models to evaluate the pharmacology of a discovery lead(s) to be the gold standard for assessing biological potency and specificity. An important requirement in SAR determination is having or developing an animal model that correlates with a disease in humans. Developing these animal models can be time-consuming and expensive, and many important human diseases do not yet have predictive animal models. Research to develop acceptable models for these diseases is a high priority at pharmaceutical companies. Many CSOs are also involved in the definition and characterization of novel *in vivo* models and, once available, offer these novel models to clients.

OUTSOURCING OF POTENTIAL FOR DEVELOPMENT CHARACTERIZATION

Completed drug discovery studies indicate that a lead(s) mediates a disease process and has potential as a therapeutic agent in humans. Is this lead now ready to be transferred to the preclinical drug development group? Or should additional, nondefinitive experiments be conducted to characterize more fully the properties of the lead(s)? If more studies are necessary, what experiments should be done? This section describes some of the experiments that could be conducted to evaluate the potential of a discovery lead to become a development candidate and provides information on CSOs that offer services in this relatively new and rapidly evolving field. These nondefinitive studies may also uncover problems that have to be resolved before starting the definitive preclinical development studies and designing the clinical trial protocols to evaluate safety and efficacy in humans. A number of questions should be

answered to effectively plan the research studies needed to assess the potential for development of a discovery lead. These questions include but are not limited to the following:

- What is the human disease indication for the potential drug candidate?
- What are the proposed route of delivery and frequency of dosing in human clinical studies?
- How long does the lead need to be in the body to elicit the desired pharmacological response?
- Will the physical and chemical properties of the lead allow delivery to the site of action?
- Can the lead be synthesized in sufficient quantity to support a drug development program?

Six scientific disciplines, shown in Fig. 2, are involved in the potential for development characterization of a lead or the assessment of which lead from a group has more development attributes and fewer drawbacks. The classic approach to discover lead optimization has been to turn the actives over to the pharmacology group. The lead with the highest potency is then selected for further development. During the past few years, a major strategic change has been the addition of screening for bioavailability or delivery, chemical and metabolic stability, and, in some cases, pharmacokinetics and toxicity to complement the pharmacology testing. A drug delivery group assesses which leads are effectively delivered by the proposed clinical route of administration. A solubility and stability group defines which leads are easily degraded and are thus not good prospects for formulation development or have insufficient aqueous solubility to first dissolve and then stay in solution after administration. The physiological distribution and disposition of these leads are studied by the pharmacokinetics group. The potential for the leads to be metabolized to inactive or active metabolites is ascertained by a drug metabolism group, which can also

conduct the drug–drug interaction studies recommended as part of the drug development process (1). An *in vitro* toxicology group evaluates the leads for cellular, genetic, and immunotoxicity. Finally, an acute toxicity study in animals may be conducted to select the lead with the optimal chance of successful development. This acute toxicity study is not an LD₅₀ study, which is not needed for overall risk assessment (2). If the pharmacologically defined actives do not meet the potential for development requirements, a pharmaceutical company has at least two choices. The first is to select the compound with the “best” overall profile and enter formal development, which will most likely result in the selected candidate being one of the preclinical or clinical losers. The other is to start the discovery process over, hoping that the next time an acceptable lead will be found and that the lost time does not result in a competitor discovering an acceptable compound that becomes first on the market.

Safety pharmacology evaluations are commonly considered to be part of the toxicology program but are in reality pharmacology studies at exaggerated doses designed to reveal the potential of an identified discovery lead(s) or drug candidate to produce adverse effects or secondary pharmacological effects on major organ systems. Safety pharmacology is commonly conducted shortly after a discovery lead has been selected for further development, and the results are used to assist in determining whether continued development is warranted, to support regulatory agency submissions, and to identify potential adverse effects. An ICH guideline (3) indicates that safety pharmacology studies include assessment of effects on vital functions such as the cardiovascular, central nervous, and respiratory systems and that these tests should be conducted before human exposure. In keeping with the current regulatory climate, most pharmaceutical companies conduct, or have a CSO conduct, a battery of tests and, at times, subdivide these tests into groups to first determine specific properties of compounds and then to more fully characterize those areas where a response is observed.

During the past few years, techniques to rapidly evaluate potential for development parameters of a large number of leads have been developed and are now offered to clients as a service by a number of CSOs. These screening methods use small amounts of each lead and, in some cases, can evaluate more than one lead simultaneously in a given sample. A few of the CSOs that offer clients more than one service in potential for development characterization and the scientific disciplines for which they have expertise are given in Table 2.

OUTSOURCING OF NONCLINICAL DRUG DEVELOPMENT

Before entering into human clinical trials, a drug candidate undergoes various preclinical studies to define and characterize its safety and disposition profiles in animal models. After entering the clinic, information on the pharmacokinetics and toxicology of the drug candidate in the relevant species (human) finally becomes available. The results from earlier drug development experiments are usually re-evaluated in consideration of this new information to ascertain whether the animal models were predictive of the efficacy and safety observed in humans. If the animal results are extrapolative, the remaining nonclinical animal studies are fairly straightforward and are conducted to provide supportive information on the safety of the drug candidate. However, if the early animal data do not extrapolate to humans, additional animal experiments may be needed to more fully understand the observed pharmacology and/or toxicology in humans. The following discussion presents an overview of the research studies conducted during nonclinical drug development, which can be divided into the broad categories of bioanalytical and analytical chemistry, formulation development, pharmacokinetics, drug metabolism, and toxicology. Some of the CSOs that offer services in a number of these disciplines are listed in Table 3.

A bioanalytical chemistry method is used to support definitive pharmacokinetic and toxicology studies after the assay has been appropriately validated. The validation experiments define acceptance and rejection criteria for the range of reliable results, the lower and upper limits of quantification, accuracy, precision, specificity, and recovery and should include appropriate stability studies (4, 5). The validated method needs to be documented in a test assay procedure, which lists the acceptance and rejection criteria for each parameter evaluated, and supported by appropriate SOPs.

Analytical chemistry and formulation development and characterization are aspects of manufacturing activities; however, these functions are critical for the successful completion of many nonclinical and clinical research studies. The section on outsourcing of manufacturing provides a summary discussion on analytical chemistry and formulation development.

Preclinical pharmacokinetic and bioavailability experiments are conducted to evaluate dose proportionality over the dose range used in toxicology studies and potential species-to-species differences in pharmacokinetic profiles. By incorporating one or two intravenous dose levels into the studies, absolute bioavailability can also be determined and information on the linearity of absorption, distribution, and disposition kinetics obtained. If more than one drug formulation is used in toxicology studies, relative

bioavailability experiments comparing the formulations can determine whether the extent of delivery is similar or different and thus can make extrapolation of pharmacology and toxicology results between animal species meaningful and useful in designing the later nonclinical studies and phase I safety and tolerance studies in humans. An important application of pharmacokinetics is determining the extent and duration of exposure, or toxicokinetics, in the test species. An ICH guideline (6) discusses the generation of toxicokinetic data to support the development of a drug candidate. Unless justified from pharmacokinetic results from humans or from toxicokinetic observations, additional animal pharmacokinetics are not usually conducted during nonclinical development. Types of animal pharmacokinetics that might be

performed include multiple-dose pharmacokinetics, bioavailability comparison when the formulation used in early toxicology studies is changed, newly identified drug candidate metabolites distribution and disposition evaluations, effect of food and time of feeding on the extent and duration of absorption, and drug–drug interactions if the animal model is considered predictive of humans.

Drug metabolism experiments in toxicology animal species are conducted to evaluate the protein binding, mass balance, and tissue distribution and to use an appropriately labeled compound. If the radiolabel is not nonmetabolically or metabolically stable, the results from the drug metabolism experiments or other studies using the labeled compound will have little if any meaning or usefulness in determining the metabolic fate of the drug

candidate. The two most common preclinical drug metabolism studies are for mass balance, which includes metabolite profiling and identification, and for tissue distribution. A routine aspect of most tissue distribution studies is whole-body autoradiography. Nonclinical drug metabolism studies that may be conducted include multiple-dose tissue distribution [as addressed in an ICH guideline (7)], additional characterization and evaluation of metabolites, and studies such as fetal-placental transfer and lacteal secretion, which provide toxicokinetic support for developmental and reproductive toxicology evaluations.

A number of preclinical toxicology studies need to be completed and documented in a regulatory agency submission before initiating human clinical trials. The number and types of toxicology studies depend on the disease type, the duration of treatment, and the country(ies) in which clinical trials will be conducted. Preclinical toxicology studies include genetic toxicology, local tolerance, immunotoxicity, and acute and subchronic tests. After human clinical trials have been initiated, nonclinical toxicology is continued with chronic toxicology studies, developmental and reproduction studies, and carcinogenicity studies. One of the most troublesome problems in interpreting toxicology results is determining whether these data are predictive of toxicity in humans. Quite often, animal toxicology may not correlate with human safety because the observed toxicities are species-specific. Species specificity is sometimes discovered early in development and can be used to design the early human trials to ascertain whether humans also manifest the observed toxicity.

An ICH guideline (3) indicates that local tolerance evaluations are to be conducted in animals using the route of administration proposed for humans. The genotoxicity (8,9) and immunotoxicity (3) potentials of a drug candidate are commonly studied shortly after a discovery lead has been selected for further development. The doses for definitive toxicology studies are defined in dose-range-finding studies, which have a primary goal of determining a maximum tolerated dose (MTD). The route of administration, frequency, and duration of dosing for this and other toxicology studies are determined from the expected clinical use of the drug candidate. When these parameters do not mimic those used in human clinical trials, unexpected findings surprises result, and the severity of the findings may be sufficient to stop development of an otherwise promising drug candidate. Most regulatory agencies require subchronic toxicity studies in two species, one of which must be a nonrodent, before the initiation of human clinical trials. ICH guidelines (3,10) suggest the

minimum duration of toxicity studies needed to support phase I, II, and III clinical trials. Regulatory agencies (2,3) require chronic toxicity studies in two species for drug candidates that are to be administered to humans for longer than 3 months. Both subchronic and chronic toxicology studies should include hematology, clinical chemistry, and histopathology evaluations. Developmental and reproduction toxicology studies are conducted to reveal any effect of a drug candidate or its metabolite on mammalian reproduction and to ascertain the potential risks to humans. These studies evaluate male and female fertility, embryo and fetal death, parturition and the newborn, the lactation process, care of the young, and the potential teratogenicity of the drug candidate. The combination of studies selected needs to allow exposure of mature adults and all stages of development from conception to sexual maturity to conception in the next generation (11,12). Carcinogenicity studies encompass most of the life span of the test species and are conducted to measure tumor induction in animals and to assess the relevant risk in humans (13–16). These studies are normally conducted concurrently with phase III human clinical trials and are required by regulatory agencies when human exposure to a drug candidate is anticipated to be longer than 6 months.

OUTSOURCING OF CLINICAL DRUG DEVELOPMENT

Drug development is a long, complicated, highly regulated process, with the clinical trial aspect of the overall endeavor being both the most time-consuming and expensive. The clinical development stage requires approximately 75% of that time and over 50% of the money expended. Pharmaceutical companies are constantly searching for ways to shorten the clinical trial stage. However, with time and cost of drug discovery and development both still increasing, these efforts have not been overly successful to date. One approach, through the ICH process, is to harmonize many of the clinical trial tasks so that research studies conducted in one country are acceptable to the regulatory authorities in other countries. An ICH guideline (17) provides assistance on some general considerations for clinical trials. This section addresses clinical drug development, which is subdivided into four phases:

- *Phase I:* Safety and tolerance evaluation in human volunteers or in a small number of patients and pharmacokinetic and pharmacodynamic studies (human pharmacology)

- *Phase II*: Efficacy in patients and dose-response and dosing regimen definition (therapeutic exploration)
- *Phase III*: Definitive safety and efficacy in patients to define benefit-to-risk relationship and to confirm the dose-response relationship (therapeutic confirmation)
- *Phase IV*: Studies performed after marketing approval, related to the approved indication, and used to obtain a better understanding of the benefit-to-risk relationship and to identify less common adverse events (therapeutic use)

For each clinical trial study conducted to support the development of a drug candidate, certain features are necessary to ensure that the study is appropriately designed and conducted; that the data generated are collected, evaluated, and interpreted; and that the results are documented in a clinical trial study report. These features can be designated clinical trial design, investigator and clinical trial site selection, clinical trial site monitoring, clinical trial supply management, data collection and management, data evaluation and interpretation, report

^aClinical trial design and investigator and site selection.^bClinical trial site monitoring.^cData management and biostatistics.^dReport writing and other document preparation.^eClinical trial supply management.^fAuditing and regulatory affairs.

writing, auditing, and regulatory affairs. CSOs have become major players in the clinical trial process. Their support ranges from designing and conducting a phase I clinical trial at a CSO's investigational site to coordinating a multinational, multisite phase III clinical trial. CSOs offering clinical trial services can be subdivided into two major classifications: those that actually conduct clinical trials and those that provide various clinical trial services. Table 4 lists a few CSOs that conduct clinical trials, and Table 5 lists some of the many CSOs that offer clinical trial support services in a variety of areas.

Phase I clinical trial studies include the initial administration of an investigational new drug to humans, usually healthy male volunteers, because the objectives of the study are nontherapeutic. However, women are now frequently included in these studies of first-time-use in humans. Close attention is given to any adverse events (AEs) that occurs and to whether these events are related to the drug candidate and dose level, or are adverse drug

reactions (ADRs). An ICH guideline (18) provides harmonized definitions for various terms including AE, ADR, serious adverse events (SAEs), and unexpected ADRs. A common practice in the first phase I clinical trial is to collect blood and urine specimens to obtain preliminary pharmacokinetic information in humans. Additional phase I clinical trials are frequently conducted later to address specific concerns such as relative bioavailability comparison when the formulation is changed; effect of food and time of feeding; potential for drug-drug interactions; pharmacokinetics in subpopulations such as the elderly, children, and ethnic groups; and possible change in clearance in renally or hepatically impaired patients.

Phase II clinical trial studies are designed primarily to explore the relationship between the dose level and frequency of administration and the efficacy and safety observed in patients with a particular therapeutic indication or disorder. Normally, a primary endpoint is

selected to evaluate the efficacy; however, secondary endpoints are often included to establish criteria for monitoring patients in the more definitive phase III clinical trials. Phase II clinical trials are commonly placebo-controlled and blinded and may include a comparator drug. An ICH guideline (19) describes a number of possible study designs and also discusses the appropriateness of each design for the patient population and the disease indication and for obtaining the desired information. The study designs include parallel dose-response in which patients are randomized to several fixed dose groups, factorial parallel dose-response in which combination therapy is evaluated, cross-over dose-response in which each patient receives each dose level, forced titration in which all patients are administered a series of rising doses, and optional titration in which patients are titrated over a range of dose levels until they reach a predefined favorable or unfavorable response.

Phase III clinical trial studies are designed to confirm that the drug candidate is safe and effective in patients with the intended therapeutic indication and are conducted in a relatively large patient population and frequently at multiple sites. The size and duration of these studies make them, along with establishing the manufacturing facility, the most time-consuming and expensive aspects of drug development. Thus, phase III clinical trials need to be carefully planned and implemented so that the resulting database of generated safety and efficacy data is sufficient to demonstrate statistically that the drug candidate can effectively mediated the disease indication without causing substantial ADRs. For phase III clinical trial studies intended to show effective treatment for a chronic disorder, an ICH guideline (20) has been issued. Still another ICH guideline (21) discusses developmental approaches for drug candidates likely to be used in the elderly because the indication is a disease of aging, such as Alzheimer's disease, or the population with the disorder includes a significant number of geriatric patients. As with most pharmaceutical companies, CSOs do not have the necessary resources at their own facilities to actually conduct multisite, multinational phase III clinical trials.

Phase IV clinical trials start after a regulatory agency has granted a marketing authorization to a drug candidate, which is now a therapeutic product. These phase IV studies need to relate to the approved indication(s) and the dosage regimen(s) that were authorized and are intended to optimize the use of the drug. Phase IV clinical trials may include epidemiology, drug-drug interaction, and sub-population studies.

Not all clinical trials, especially large, multisite, multinational phase III studies and phase IV postmarketing surveillance, pharmacoeconomic, and quality-of-life

studies, can be conducted at a CSO facility. These types of studies, and many phase II efficacy studies, are conducted in research- or university-based hospitals or other investigational sites where a sufficient patient population with the disease or disorder to be tested is available. A number of CSOs offer services to support clinical trial studies that are implemented at one or more clinical trial sites. These services can be broken down into relatively broad categories, which are summarized later.

CSOs assisting clients with clinical trial design need to be an extension of the client's project team and have access to all the data to assist in developing a realistic clinical trial package to determine the safety and efficacy of a drug candidate. In addition to assisting clients with clinical development plans and preparing clinical trial protocols, many of these CSOs also offer clients services for the preparation of CRFs, investigator brochures, IRB and IEC applications, and other clinical trial-related documents. Unless a clinical trial is being conducted at a predetermined site, selection of the clinical site(s) and the investigator(s) who will be responsible for the clinical trial is the next step. The pharmaceutical company is ultimately responsible for all research studies conducted during the development of a drug candidate. However, the clinical trial investigator is a key player (22) and has to have certain qualifications to assume a number of responsibilities. The next step is training of site personnel in the specific aspects and requirements of the study protocol. This training can be critical, especially when the study uses specialized or novel techniques for evaluating safety and/or efficacy. Clinical trial monitoring assists in ensuring that difficulties or problems are detected early and that their occurrence or recurrence is minimized. Overseeing the quality of a clinical trial involves checks of various aspects that may include ascertaining whether the study protocol and SOPs are being followed, whether GCP regulations and other regulatory agency regulations are being followed, the acceptability of data being generated and listed on CRFs and other clinical trial documents, the success in reaching planned patient accrual targets, success in keeping patients in the trial, and tracking clinical trial supplies. An ICH guideline (22) offers guidance on the various aspects of monitoring.

The proper management of the drug candidate and other products, such as comparator drugs and placebos, is in many respects as important to the success of a clinical trial as the care and management of the patients. The clinical trial supplies need to be appropriately characterized, manufactured in compliance with GMP regulations, and, if applicable, coded and labeled to protect the blinding of the

clinical trial study (22). Outsourcing to CSOs or other companies of manufacturing and formulation development research is a common practice. This outsourcing does not relieve the clinical trial sponsor of responsibility for ensuring clinical trial supplies meet the requirements for the proper conduct of a clinical trial.

The primary focus of the data collection and management process is to provide a guaranteed, quality-assured, final database, which is accomplished by standardized strategies for handling data, verification of data, comparing and repairing data entries, and verifying the accuracy of the data. Inaccurate or incorrect clinical trial data can result in an otherwise successful clinical trial being erroneously interpreted for safety and/or efficacy parameters. Three ICH guidelines (18,23,24) address safety data management issues. The data collected from a well designed, well conducted clinical trial are evaluated to ascertain the benefit-to-risk relationship for the purposed therapy. When the patients who received a drug candidate have the disease manifestations completely eradicated and experience no other effects while patients treated with a placebo have a continuation of the disease process, the evaluation is not difficult. However, that is rarely, if ever, the case, and evaluation requires detailed statistical analysis of the collected data. An ICH guideline (25) covers statistical issues related to the scope of clinical trials, design techniques to minimize bias, types of clinical trial designs, conduct considerations, data analysis for efficacy, evaluation of safety and tolerance, and reporting.

Pharmaceutical companies are constantly bombarded with advertisements and brochures from CSOs and other groups that promise unrealistic speed in clinical trial design and management to expedite clinical development. What is missing from this picture? The compiling of the nonclinical and clinical findings in a detailed, well designed, believable story that results in the production of a high-quality regulatory agency submission for marketing authorization. This effort requires the expertise of scientific and medical writers who use clear, concise writing to share the science of drug development. All data and results, both positive and negative, generated during the development of a drug candidate need to be included. An ICH guideline (26) offers assistance in the generation and compilation of clinical trial study reports that are acceptable to all ICH region regulatory agencies. Many CSOs offer scientific and medical writing services, and some consider their medical writing capabilities to be more than just another service offered.

The audit of a clinical trial is independent and separate from routine clinical trial monitoring and quality-control functions. An audit is an aspect of quality assurance and evaluates clinical trial conduct and compliance with the

study protocol; applicable SOPs; GCP, GLP, and GMP regulations; and applicable regulatory agency regulations (22). A clinical trial auditor is to be independent from the clinical trial. Because a clinical trial auditor(s) cannot have been involved in the study, clients who use a CSO to support the various aspects of clinical drug development and then contract with the same CSO to audit clinical trials need to ensure that the auditor(s) is truly independent. To achieve this goal, clients may contract with one CSO to support the clinical trial and another CSO or a qualified independent consultant(s) to conduct the audit. An estimated 80% of the regulatory agency approval process focuses on the clinical trial sections of a marketing application submission. To ensure that these, and other, sections are complete and meet the perceived specifications of the regulatory agency reviewers, most pharmaceutical companies have established regulatory affairs groups. These groups commonly assist drug development project teams and company management in defining and implementing regulatory strategies for the various aspects of drug candidate development, offer advice and recommendations on regulatory issues applicable to the countries where marketing approval is being sought, and serve as the primary contact between the company and regulatory agencies. Some CSOs offer regulatory affairs capabilities.

OUTSOURCING OF CONTROL, MANUFACTURING, AND CHEMISTRY

After clinical trials, the next most time-consuming and expensive aspect of the drug development process is the synthesis and characterization of the drug substance and drug product, i.e., the manufacturing process. A manufacturing process that is inappropriately designed, implemented, and controlled can kill a promising drug candidate or active pharmaceutical ingredient (API), which is the term used by most manufacturing groups, as easily as can life-threatening adverse effects or insufficient biological activity. A drug candidate that is costly to effectively produce results in high prices to patient, that, unless the drug is the best or the only therapy for a disease indication, lowers the market share and thus the revenue to the pharmaceutical company. Similarly, a complex manufacturing process that is difficult to control may result in API variations, in both amount and impurity profiles, that can hinder regulatory agency approval unless the manufacturer can prove that the production processes are being following and are producing the same material in each production batch.

The manufacturing process is frequently changed to improve yield or decrease impurities. To ensure the drug substance is the same after processing changes, manufacturers develop and validate characterization procedures to demonstrate and document that the changes have not affected the material being produced and that no previously undetected impurities are present.

Many pharmaceutical companies outsource one or more of the control, manufacturing, and chemistry (CMC) processes, for which numerous regulatory agencies guidelines are available. Reasons for this outsourcing include but are not limited to:

- Avoiding capital investment in facilities, equipment, and personnel;
- Avoiding the need to establish and maintain a GMP manufacturing facility;
- Gaining access to additional capacity and technology;
- Accessing a contractor's expertise; and
- Expediting the time to market

Some CSOs that offer multiple CMC services to clients are listed in Table 6. These services have been subdivided into the major categories of manufacturing, raw materials, formulation development, method development, stability, packaging, and auditing.

The manufacturing process starts when the discovery scientists synthesizes a compound that has biological activity. The techniques used are usually sufficient to produce milligram to gram quantities for pharmacology studies but are rarely adaptable to the large-scale synthesis necessary for generating the much larger amounts of material needed for formulation development and preclinical and clinical studies. Shortly after a discovery lead is designated a preclinical drug candidate, the manufacturing group begins the research studies necessary to scale up the laboratory bench synthetic procedure to a larger, or manufacturing, process. Whether the drug substance is a small organic molecule or a macromolecule, the procedure may and usually does undergo substantial modification during scale up to commercial production. A few of the items that are evaluated during the establishment of a manufacturing process include:

- Identifying synthesis and formulation methods, including definition of equipment, processes, and scale of production;
- Defining and validating processes for fill, finish, and packaging;
- Determining procedures for waste disposal, including appropriate environmental assessments; and
- Determining the number of batches required to support development program and product launch.

One of the most important aspects of the manufacturing process is documentation and document control. Each step in the process, whether the results are positive or negative, needs to be evaluated and documented to show that the manufacturer understands what is happening and can control the synthesis, purification, formulation, and packaging of the drug product. Some of the documents needed include:

- Chemistry, manufacturing, and control documents;
- Appropriate standard operating procedures;
- Validation protocols for methods and processes;
- Progress and final reports for methods and processes; and
- Regulatory documents, such as IND, yearly updates, and NDA.

The raw materials used in the synthesis, purification, and formulation of an API are critical for the successful manufacture of a drug product. The supplier or vendor of each component and intermediate has to be identified and certified, commonly through a detailed site visit. The amount, timing, and cost of these supplies are negotiated so that the key ingredients are available when needed. Another important item is determining the shelf-life of each raw material to ensure that the ingredient has not deteriorated from the time of purchase to the time of use.

Once the drug candidate is available, formulation activities are initiated to develop a suitable dosage for administration to animals and, later, to humans. Depending on the route of administration, formulations may be solutions, suspensions, aerosols, creams, or solids. Because formulation ingredients can affect the delivery profile of a drug candidate, in some cases adversely, using a preclinical formulation that closely resembles and mimics the proposed clinical formulation is highly desirable. Thus, preformulation studies need to be conducted as early in the development process as possible. The formulation process usually continues throughout the development process, with changes made to improve stability, enhance delivery, or mask the taste or appearance of the drug product. Depending on the extent of the formulation change, additional nonclinical and clinical studies may be necessary to determine if the revised formulation has the same characteristics as the original formulation and, if not, what the extent and nature of the difference are.

Analytical chemistry methods are used for chemical characterization of the drug substance and drug product. This characterization includes qualitative tests for structural identification and for impurities, degradation products, and contaminants (27–29). Characterization relies on well characterized, validated, analytical

^aManufacturing including process development and validation.^bRaw material including procurement and testing.^cFormulation development and characterization.^dMethod development for drug substance and drug product characterization.^eStability testing of drug substance and drug product.^fPacking services for drug product.^gGMP audit of chemistry, manufacturing, and control processes.

chemistry methods, which may include USP methods such as residual solvents, moisture content, residue on ignition, and thermal determinations and drug candidate-specific methods such as identification, concentration, impurity profiles, solubility profiles, and stability under various temperatures and conditions. For proteins and polypeptides, additional characterization is necessary. Several ICH guidelines (30–37) have been issued on characterization and discuss stability testing, including photostability, impurities, residual solvents, and test procedure and acceptance criteria specifications (33, 34). Quantitative analytical chemistry methods provide information on drug substance concentration, impurity profiles, and stability profiles. ICH guidelines (35, 36) for validation of analytical chemistry procedures address experiments to ascertain and set acceptance specifications for specificity, detection limit, quantification limit, linearity, range, precision, accuracy, and robustness. Analytical methods need to be validated for each sample type to be analyzed.

Stability testing determines how a drug substance or drug product may change with time under various conditions, such as temperature, humidity, and light and defines storage conditions and shelf-life. A number of ICH guidelines (30, 32, 37) describe and discuss stability issues and testing requirement for NCEs and macromolecules. These guidelines provide manufacturers and CSOs with acceptance specifications for

accelerated and long-term stability studies. In addition to the drug substance and drug product, stability assessment is frequently conducted on raw materials, key intermediates, formulation excipients, and packaging materials.

After the drug product is prepared, the next step is packaging and labeling the material. Packaging requirements depend on the final drug product (solid, suspension, liquid) and the clinical indication (hospital, physician office, or home use). For liquids to be dosed parenterally, sterility of the drug product is important and validated, and aseptic filling procedures are necessary. For other dosage forms, specialized equipment may be needed to place the drug product into the desired package. Compatibility of the drug product with any packaging material, such as vials, inner liners, and closure systems, with which the product comes into contact needs to be evaluated. Proper labeling and package insert information is critical for the proper use of the drug product. The label and package insert provide physicians, pharmacists, and patients with information on:

- The drug substance, drug product, and formulation excipients;
- Clinical pharmacology and the biological action of the drug substance;
- Indications and usage for which the specific drug product has been approved;

- Contraindications for when the drug product should not be used;
- Warnings and precautions on the use of the drug product;
- Adverse reactions reported and attributable to the drug substance;
- Overdosage effects and treatment to counteract the effects;
- Dosage and administration specifications for the drug product; and
- How the drug product is supplied and appropriate storage conditions.

Audits are conducted to ensure that the manufacturer—either a pharmaceutical company or a CSO—has appropriately defined and documented the various processes and methods required to produce the drug substance and drug product and has the necessary personnel and facilities to conduct and control the manufacturing process and to determine whether GMP regulations are being followed. As with clinical trials, the pharmaceutical company developer is responsible for the manufacture of the drug substance and drug product, whether these activities take place at the company's facilities or are outsourced. Audits, whether conducted by regulatory agencies or by the developer, determine that the processes are under control and in compliance with GMP regulations. Problems discovered during audits can usually be resolved, and to prevent regulatory agencies from finding these areas of concern, pharmaceutical companies use their internal QA groups or their contract with the CSO or independent consultant to conduct GMP audits of the CMC aspects of drug development. As with its role in clinical trial auditing, the auditors have to be independent of the processes being audited, and at times, clients outsource auditing of a manufacturing CSO to another CSO that provides GMP auditing services.

VIRTUAL DRUG DEVELOPMENT ORGANIZATIONS AND CONSULTANTS

Another relatively new player in the drug discovery and development arena is the virtual drug development organization (VDO), which, like the CSO, offers pharmaceutical companies support in developing discovery ideas into therapeutic products. However, VDOs do not offer laboratory services, but provide clients with coordination of the various drug discovery and development activities necessary to characterize a drug candidate and produce the compound in sufficient quantity for

nonclinical, clinical, and marketing efforts. This coordination is accomplished by designing and outsourcing the research studies to CSOs and then compiling the results generated into regulatory agency submissions. VDOs operate in one of two ways. One is to contract with the pharmaceutical client and serve as an extension of the client's program. The other is to out-license a drug candidate from a pharmaceutical company or university technology transfer group. In both cases, VDOs interact closely with CSOs. Pharmaceutical firms need to evaluate VDOs using the techniques and requirements used to select and monitor CSOs.

Consultants have supported the pharmaceutical industry for many years and provide expert advice on the many aspects of the drug discovery and development processes. This advice includes assisting in the selection and monitoring of CSOs and in the interpretation of results from outsourced studies. Pharmaceutical companies select consultants in a variety of ways, the most common being the "good-old-boy" network, in which a pharmaceutical company executive knows, or has a friend who knows, someone who is now a consultant, commonly a retired pharmaceutical executive, a former regulatory agency reviewer, or a pharmacology professor at a university. Is this the optimal means of identifying an expert? Probably not, if the company wants an expert with knowledge and experience in a particular area(s) research, such as drug metabolism or drug product stability. The techniques outlined above for selecting a CSO should also be used for evaluating consultants, with research area experience, integrity, and communication skills probably being the most important aspects. Choosing a toxicology or clinical pharmacology consultant to assist with evaluating human pharmacokinetic results may prevent the data from being used effectively to design additional nonclinical toxicology or clinical trial studies.

EMERGING TRENDS

Major changes have occurred, and are occurring, in the pharmaceutical industry and in the drug discovery and development processes. They have caused numerous changes in the way CSOs provide support services to drug developers. What can be expected in the future? Are more changes on the horizon, and, if so, what might they be and how will they affect pharmaceutical companies and their service providers? Although predicting the future is usually quite inaccurate and often misleading, some trends, based on recent events, may be extended into the near future.

For pharmaceutical companies, present trends indicate that:

- Mergers and acquisitions will result in formation of more mega-pharmaceutical companies. Reasons include the desire to have a more global presence, to enter into a therapeutic area with previously established research staff and drug development pipeline, and to obtain novel technology to assist in accelerating drug discovery and development. Whether these mega-firms have a better chance than midsized or small pharmaceutical houses in obtaining marketing approval for major therapeutic products is unknown.
- Numerous new companies, primarily biotechnology firms that hope to turn a discovery idea into a therapeutic product, will be formed. Funding for these firms will be difficult to obtain, will come primarily from venture capitalists and government grants, and will be insufficient to take a discovery lead through complete drug development. Most of these start-up companies will attempt to outlicense or sell for much-needed cash and future royalties their discoveries to pharmaceutical companies or VDOs. The further these small companies are along in the drug development process will determine how much they will receive for their discoveries. A number of companies, approximately the same number that are formed, will go out of business, merge, or be acquired when their discovery does not result in drug candidates with the necessary attributes to become therapeutic products.
- The ICH process will provide more standardization to the requirements for the worldwide development of drug candidates. A global marketing application package that meets the requirements of most regulatory agencies and that includes nonclinical, clinical, and manufacturing aspects will be defined and accepted.
- Even the best efforts of drug developers will not reduce the time and cost of drug discovery and development. However, as novel drug discovery and potential for development characterization techniques are put into place and the ICH process is more fully implemented, the time and cost will not increase as rapidly as in the past.

For CSOs and other support groups, the trends noted previously offer nothing but opportunities. The prospects for CSOs are very bright, and CSOs that capitalize on the present and future needs of their clients will be highly successful. Trends for the CSO industry include that:

- Pharmaceutical companies will increase their outsourcing efforts;
- Drug discovery and potential for development characterization services will be high-growth areas because these fields are presently bottlenecks, and the situation is not expected to get any better;
- CSOs offering primarily or exclusively nonclinical drug development services will have to broaden their capabilities to attract and maintain clients,
- Clinical CSOs will have more studies than they can support effectively and will most likely expand to meet the needs of their clients,
- Clinical CSOs that provide services in a number of aspects of clinical trials and have a worldwide presence will grow and prosper,
- More mega-CSOs, such as Quintiles and MDS, will emerge. Likely candidates are these mega-CSOs will offer clients many, but probably not all, services needed for drug discovery and development. Some of these large CSOs may attempt to become pharmaceutical houses and use their considerable expertise to discover and develop compounds obtained through their own efforts or by inlicensing,
- The CSO field will not be dominated by the mega-CSOs. The present and future bottlenecks experienced by pharmaceutical companies will result in more CSOs, not fewer. These new CSOs will offer clients specialized services in drug discovery and potential for development characterization to evaluate multiple discovery leads simultaneously,
- As pharmaceutical companies merge and continue to "right-size," CSOs will become more a true partner and less a pair of hands to complete tasks. The clients will have to share more scientific information, both positive and negative, to the service providers that, in turn, will need to learn more about the entire drug discovery and development process for these partnerships to be effective and beneficial for both parties.
- CSOs will be a primary source of employment for new graduates and for down-sized pharmaceutical company employees in various scientific disciplines. The new graduates will bring in the latest academic technology to assist in expanding or defining novel services to be offered to clients. These young, highly motivated employees will learn the more applied science of pharmaceutical development from the former pharmaceutical company employees.

Whether many or all of these potential trends will occur in the near future is not known. One thing is certain, change will happen. Those pharmaceutical companies and their CSO partners that embrace change and adapt to novel

ideas and approaches to improve and possibly shorten the drug discovery and development processes will prosper. Companies that do not or are unwilling to embrace change will most likely become a memory. However, even a bad memory can offer guidance and be used to improve the process for finding novel therapeutic agents to treat one of the many human diseases or disorders that presently have only marginal or no effective treatment.

PAPERLESS DOCUMENTATION SYSTEMS

INTRODUCTION

The fundamental purpose of documents is communication. Specifically, documents enhance the flexibility of communication. Documents improve the ability to transmit information in two ways. First, a document freezes a sender's message in time so that it may be accessed later. The wall of a cave marked with pictographs, a carved stone tablet, a photograph of the cave wall, a creased paper bag containing a shopping list, as well as a phonographic recording of a piano concerto all record information that persists through time beyond the act of its creation. The second way in which documents make our communications more versatile is by allowing the sender's message to travel through space independently of the sender. With the exception of the cave wall, each of the above examples is more or less portable. It is portability that gives documents the capacity to communicate across space as well as time.

By packaging a sender's message in such a way that it may be accessed by physically scattered recipients at any time after the original recording, documents enable marvelous things to happen. While proscribing real-time exchange between a message's sender and recipient, a physical record gives to ideas a life that they often would not have if merely spoken or performed once in time. Governments, religions, and much of society depend crucially on the existence of an ongoing exchange with certain key documents (1). On a smaller and more immediate scale, documents enable us to get things done in ways and on a scale that spoken words alone do not. Indeed, by allowing us to communicate across vast reaches of time and space, documents increase the coordination and scope of communication, thereby enabling tremendous feats of collaboration.

Perhaps more than other industries, pharmaceutical manufacturing and marketing depend on exquisite levels of collaboration among many different spheres of activity, ranging from analytical chemistry to clinical medicine, operations research, business, and the law. This complex coordination and a strict regulatory

landscape, which ultimately dictates the viability of a pharmaceutical product, demand that all scientific and business decisions from discovery through postmarketing research be rigorously and thoroughly documented. The sheer volume of written procedures, forms, analyses, reports, and correspondence that must be managed across a single product's lifecycle is enormous. When one considers enterprise-wide management of documentation supporting a portfolio of dozens of drugs in various stages of development, the numbers are truly staggering. Although regulatory authorities have recently issued comprehensive regulations (2–4) and guidelines (5–7) on electronic records management, these standards and the predicate rules on which they are based could rapidly become outdated in the evolving world of computing and wireless data exchange (8).

Until recently, document management in an enterprise has been organized around distinct efforts involving the control of three kinds of paper document (forms, reports, and manuals) and the administration of the folders and archiving procedures used to manage them (9). A number of economic and technological forces over the last quarter century have changed business in such a way as to strain the traditional methods of document management, if not render them wholly obsolete. For one thing, improvements in organizational, manufacturing, and communications technology that have compressed production cycles and decreased the time from concept to market in nearly all industries have also yielded a corresponding acceleration in demand and consumption. With improvements in communications and techniques of distribution come unavoidable increases in the volume of business transactions (10). Speeded up markets beget more business, which necessitates more efficient management of ever more documentation. As computer technology has been introduced into business environments over the last 25 years to adapt to this quickening pace, the system designed to manage paper has met with great difficulty storing electronic documents as well (11). Computing and communications technology is changing the fundamental status of documents.

EVOLUTION OF DOCUMENTATION TECHNOLOGIES

Initially, the implementation of a paperless documentation system in an enterprise is driven by a need or mandate to eliminate paper, economize the use of physical space, improve the efficiency of document retrieval, or otherwise improve the storage of information assets. Paper document management has referred to the storage, modification, and retrieval of documents that distinguish themselves from each other in terms of content, purpose, or format. The emphasis is on the introduction of a system that provides a storage solution. The true strength of most electronic document management systems, however, lies beyond the simple capacity to warehouse digital representations of paper documents.

During the 19th and 20th centuries document technologies have followed an evolution that has repeatedly and alternately focused on document production, reproduction, and distribution. The first long wave of innovation was centered around the means of producing text. From as early as the fourteenth century, at least one hundred writing machines were invented before the Sholes and Glidden typewriter was produced by the gunmakers Remington and Sons some sixty miles west of Albany in 1874 (12). The second major development in the history of modern document technology sought to enable the rapid dissemination and reproduction of paper documentation and is marked by the Haloid (later Xerox) company's introduction of the photocopier around 1960 (13). In the mid-1960s, by way of the IBM Selectric typewriter, which had magnetic tape storage, and the text editor, which handily managed unformatted text for machine processing, the third evolutionary step brought the management of all aspects of the composition and formatting of individual documents in the form of the WYSIWYG word processor (14). By the mid-1990s, the word processor had effectively satisfied all needs surrounding the efficient production and stylistic control of single documents within a given operating system or platform. Concurrent with the improvement of word processing technology, much attention was paid to enhancing the distribution of textual information to disparate locations across computer networks. The shift in attention took place on two fronts, looking first to the distribution of formatted content across multiple platform-independent systems and then to managing the storage and retrieval of, as well as the complex relationships among, large volumes of documents. 1990 saw Tim Berners-Lee create the first web browser and a simple markup

language that would become HTML (hypertext markup language) at the European Laboratory for Particle Physics (CERN) to enable collaboration among disparately located scientists (15). This innovation is, in fact, not so new. It was actually presaged nearly half a century earlier by Vannevar Bush in an article written for the *Atlantic Monthly* that described his "memex" machine, which bears an eerily prescient resemblance to today's World Wide Web and the practice of hypertext linking (16). By the mid-1990s innovations in document warehousing and distribution were built atop mature relational database technologies and the ability to efficiently link document objects stored on a server platform with their associated indexing attributes in a database (17).

The evolution detailed above has alternately expanded and narrowed its focus, shifting from the domain of the document itself to the interstices between multiple documents and their authors and consumers. The development emphasis has cycled back and forth between the production of documents and the reproduction and distribution of documents. As we move into the 21st century, the prevailing trend in document technology appears to be moving in the direction of fusing the cycles of document production, reproduction, and distribution. As much as business allows, documents will soon be designed to allow their transmission, reuse, and machine processing in a simple fashion. Indeed, more and more, business models will be forced to adapt to a landscape that operates on such "documents." The need for immediate access to "decisionable data" in drug development, the need to control development costs, the need to shorten development times to protect patent life, the need to retrieve and analyze data for rapid response to regulatory and legal inquiries are but a few scenarios making the case for adapting to the new landscape in the pharmaceutical industry (18).

DOCUMENT MANAGEMENT PRINCIPLES

The traditional records management model is based on cabinets, folders, and files (9). This physical model was given its logical extension in the first electronic document management systems, where files were placed into virtual cabinets and folders.

File Room Model and Security

Security models for documents are all based on controlling who can see documents, who can create or edit documents,

and who can delete documents. Securing these rights is implemented at numerous levels. It is illustrative to consider these in terms of a physical library or paper-based file room (9). First, you may need proper credentials simply to get in and browse the holdings. Second, once you've gained admittance to the filing area, your ability to view certain kinds of records may depend on your job title or departmental affiliation. Third, assuming you have rights to view a specific record, you may have permission only to view the final file (as opposed to a draft) under observation in the file room itself, and you may not be permitted to make a copy. Finally, if you are permitted to check the document out of the file room for a limited time, you will be required to sign your name to a dated logbook. Each of these constraints on your ability to interact with the holdings preserves the likelihood that files will remain unchanged for the next requestor and holds you accountable should they not.

Input–Output Model and Quality Control

Traditional document management rests on a very simple input–output model. An enterprise seeks to manage the storage of documents (input) in such a way that their retrieval (output) is simplified. The real goal is speedy retrieval of documents. Their intelligent storage is the means to achieve it. In most enterprises it will not do to sacrifice accuracy for speed, so the process must first attend to the security, integrity, and authenticity of the data being served. The enterprise must build in mechanisms to control and track input and output processes, which include versioning, searches, and collaborations or workflows. In the paperless environment, speed, intelligent storage, and accuracy of data and searching remain of paramount importance. As the paperless environment grows in volume and complexity, meeting these needs becomes increasingly difficult.

ELECTRONIC DOCUMENT MANAGEMENT SYSTEMS (EDMS)

Goals and Objectives

Electronic document management concepts have provided the bridge between traditional paper-based information management and the threshold of a new information age. The putative goals of moving from a paper-based to a paperless documentation system are to improve business processes and ultimately to enhance enterprise

performance and the bottom line by exploiting the numerous advantages of leaving paper behind (18). The core objectives that support the attainment of those goals include the following:

- Increase efficiency and effectiveness by stewarding the generation of paper and electronic documents within the individual's scope of control;

- Increase productivity by optimally using, reusing, and recycling enterprise documents where possible;

- Increase the consistency of classification, indexing, and retrieval of documents;

- Increase the sharing of documents within an organizational unit, and between and among organizational units, while maintaining necessary access controls;

- Preserve decision and accountability trails for documents;

- Automate the retention and disposal procedures for document review and retirement. Given these goals and objectives for paperless systems (19), it is perhaps helpful to look at the specific business and functional requirements that drive and enable them.

System Requirements

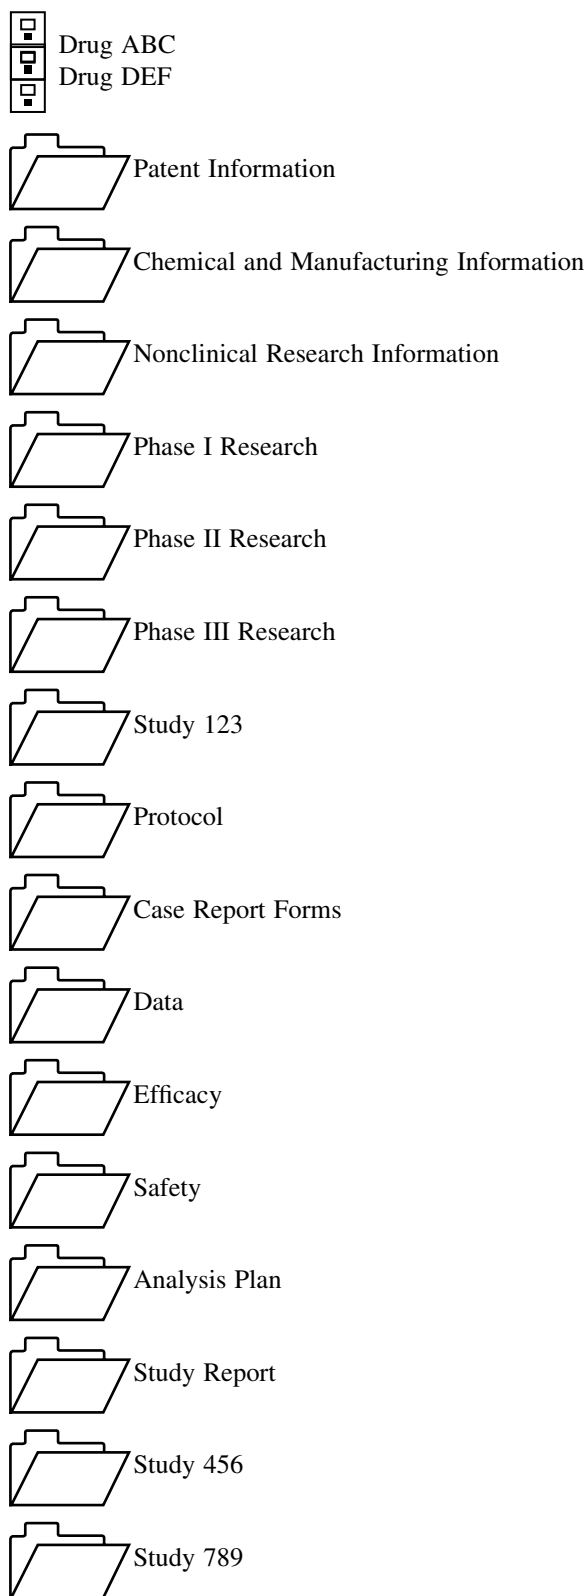

Before implementing any piece of technology in a business setting, it is necessary to define thoroughly both the business and functional requirements for the system. Business requirements describe, independently of technology, the high-level activities and processes that must be performed or enabled and the constraints that must be met by the system. Functional requirements outline in greater detail the lower level operations that must be performed and the constraints on the mechanisms for performing them.

Organization requirements: cabinet/folder structure

The most obvious business requirement for an EDMS is that it should enable the user to easily place and retrieve the items stored within. This means that files should be stored in the repository in an organized hierarchical file structure. Drug documents must be automatically stored in the appropriate location in the file structure based on their identifying information. Rather than having to manually place a file by navigating the entire hierarchy, which may be quite large in an enterprise with hundreds of compounds in various stages of development, a file could be placed following the entry of key content words or key file attributes (indexing information or metadata).

For a system managing documentation pertaining to the full life-cycle of drug development, including the conduct

of clinical trials, a useful cabinet and folder hierarchy might resemble the following:

Input requirements: Creating and importing documents

The true business value of an EDMS is realized to the extent that it serves as more than just the terminus for document-related activities in an enterprise. To fully realize its goals, an enterprise paperless documentation system will perform functions across the entire document life-cycle. In addition to the storage of existing documents, users with appropriate system privileges must be able to create new electronic documents from within the electronic document management system. The system must explicitly support the file formats used by the business, which typically include word processing, spreadsheet, graphics, and database files.

An enterprise EDMS must be flexible enough to accommodate documents that do not originate within the system. It must be possible to import documents whether they are electronic or paper in format. Technologically speaking, there are no constraints on the files that can be stored in modern electronic document management systems. It should be noted, however, that certain file types (e.g., databases) cannot be rendered meaningfully to certain standard immutable display formats (e.g., PDF) and will often be viewed by default as read-only in the authoring application.

Modification requirements: Version control and document lifecycle

The ability to track changes in a fully rationalized manner is central to achieving enterprise objectives related to efficiency, data integrity, and accountability. To facilitate control over the full development lifecycle of documents,

users with appropriate system privileges must be able to check out, modify, and check in documents.

In paper-based archives, questions about a document's authenticity or official status are usually answered by the surrounding policies and institutional mechanisms which dictate that only final and official documents are kept. In an EDMS environment, where document drafts are managed alongside their finalized counterparts, it is important to implement controls to ensure that the current version of a document is retrieved by default and that prior versions are retrieved only on explicit request. This is critical to both archiving and collaboration and workflow. The EDMS must implement a policy of nonreplication of documents and must also judiciously apply permissions to control changes in a document's life-cycle status. The system should distinguish between draft, review, approved, and final versions of a document and implement business rules defining security for the document based on its life-cycle status. For example, when a document is assigned a status of FINAL, users may view the document, but no one is permitted to modify it. The controls afforded by an EDMS should ensure confidence in answering questions about the official status or current version of a document.

Retrieving requirement: attributes and searching

In the digital age, ideas and information will be reprocessed and reused. Their portability and, consequently, their usefulness are dependent on the ability to find their particular data bit streams within a vast universe of binary number sequences. As the mass of documents in an enterprise EDMS grows and the filing structure that accommodates it both broadens and deepens, retrieving any specific item from the repository becomes more difficult. Speedy and accurate search and retrieval are achieved by allowing searches based on document content, attributes, or both. Users must also be able to save their queries for future reuse and store their queries in a centrally administered, single location. A simple FIND function must allow users to search either all versions of files or to restrict a search to only current versions of files. The system must validate and maintain a controlled list of category values and a controlled list of status values.

Searching for documents based on document content are "key word" searches using words or phrases. Document attributes, on the other hand, are summary information about the document, such as author's name, protocol number or drug name associated with the file, document title, modification date, business category, sponsoring business unit, document development milestones, project name, version status, version number, by which a document can be indexed. A document's attributes must uniquely identify it in the system. These

metadata allow for this intelligent searching through vast amounts of documentation. What metadata are captured at the time of document filing depends largely on the business requirements for searching through documents, though there are certain generic metadata that seem to apply across various settings.

As a company auditor, imagine we are confronted with the unwelcome but necessary chore of revisiting all approved contracts for the past five years undertaken by a particular division and involving a particular kind of endpoint analysis, "EP analysis," for compound XYZ. We need only briefly contemplate the prospect of searching through a paper-based archive for all occurrences of terms, say, "EP analysis" and "approved," to appreciate both immediately and fully the power of an electronic document management system. Even if we are able to physically separate all the paper contracts generated by the business unit in question, there is potentially still staggering work to be done in determining whether they involve the specified analysis or not. In a fully text-indexed EDMS with metadata indexing that anticipated the need for searching by business unit and the document type "contract," such a search would be trivial.

The richness of a business dialect probably varies directly with the specialization of the vertical market in which it competes. The ability to retrieve all relevant documents without having to specify every variant of equivalent terms can be of critical importance in performing effective and efficient searches. Such a method of searching through documents is the beginning of a movement away from the simple matching of string literals and towards the mining of data and meaning. The pharmaceutical industry is a striking example of an industry totally dependent on the ability to mine data and information for its economic viability.

In the end, EDMS systems allow for most effective searching when the filing hierarchy, indexing attributes, and some combination of full-text index, synonyms, or relevancy criteria are used in concert to specify the context around a particular search.

Output requirements: Viewing, printing, and exporting documents

Users with appropriate system privileges must be able to export documents in their native formats to any local or remote file systems to which they have access. Documents must be available for viewing in a standardized read-only format. Users must be able to view documents even if they do not have the native application. Users must also be able to match a printed or exported document to the original source file within the EDMS by means of unique system-generated identifiers referred to as watermarks.

Watermarks must not obscure any information on the document and must be in a standardized format. Watermarks must not be obscured when the document is bound.

Once a document is housed in an EDMS, it is very easy to publish it in many different places and still adhere to the principle of nonreplication. Enterprise intranets, local area networks (LANs) and wide area networks (WANs), make it possible to offer direct access to a document repository throughout an organization without requiring a physical replication of the database. Industrial strength document management systems are scalable and a single instance can support thousands of users. Also, even if the underlying filing hierarchy does not suit the needs of all customers, most EDMS packages allow for the repurposing of documents through a facility sometimes referred to as "virtual documents." This permits documents to be stored once in the repository but presented to various users in any number of ways. For instance, if both a clinical team and a biometrics team have their own standard document sets but each requires a copy of an investigator CV, two differently structured virtual documents can be created that each point to a single copy of the CV. Virtually all EDMS systems on the market today can serve as secure back-ends to web portals, enabling access to files stored in the system via ordinary HTML hyperlinks.

Electronic document management systems have the ability to distribute documents based on permissions or access control lists (ACLs). Document consumers can be notified automatically of a document's availability in the system. Once a file's status is updated to "final" or "approved," a message can be automatically sent to members of a distribution list alerting them that it has been published. Access to the document can be further streamlined by attaching to the email a pointer to the file in the EDMS.

Users with appropriate system privileges must be able to view documents. Typically, documents to be viewed in an EDMS are presented as read-only files, either in the authoring application or a standard immutable file format such as TIFF (Tagged Image File Format) or Adobe's portable document format (PDF). By virtue of its flexibility and platform-independence, PDF has become the storage standard in contemporary electronic document management systems (5). Most systems will automatically create PDF files and provide the PDF rendition in response to a user view request.

Workflow requirements: Collaboration and electronic approval

The pharmaceutical industry is a collaborative enterprise. An EDMS must provide the ability for users to electronically route documents with embedded messages

to other users electronically for review and approval. The system must enable routing of multiple collaborative document types, such as SAS logs, lists, tables, graphics, datasets, and program files. The inclusion of routing features that enable files to be sent among users for review, annotation, and editing obviates the need for the handoff of multiple paper copies via interoffice mail. Moreover, the integration of such routing utilities with standard office email packages makes it possible to notify collaborators that an item is ready for review in the EDMS environment.

The capstone to fully electronic workflow and, indeed, the key to eliminating paper handoffs from the workplace is some kind of electronic approval facility. Electronic approval can be implemented in several ways, each of which is meant to substitute for a handwritten signature. Broadly construed, electronic signatures are linked to their owners in by verifying one of three things: (1) what the owner knows; (2) what the owner has; and, most secure, (3) what the owner is.

Encryption and certificate authorities

With the growth of electronic systems for creating, maintaining, and storing an organization's critical business documents, and with growing numbers of those documents existing only electronically, our electronic identities are forced to grow. Indeed, with increased mobility within and across job sectors, these electronic identities may span more than a single organization. In this light, encryption and digital certificates present an appropriate final issue to consider when confronting the security and validity of electronic approval. Certificate authorities (CAs) are the digital world's equivalent of passport offices. These businesses issue digital certificates and validate the holder's identity and authority. Public Key Infrastructures (PKIs) and digital certificates are most trustworthy when they are vouched for by a trusted certificate authority. CAs embed an individual's or an organization's public key along with other identifying information into each digital certificate and then cryptographically "sign" it as a tamper-proof seal, verifying the integrity of the data within it and validating its use (20).

What the signatory knows: This method of approval is the simplest to administer, because it relies on the assignment of unique ID and password combinations to every member of an enterprise, a practice that is already quite common as a result of the widespread application of networked computing.

What the signatory has: Here, approvals are issued by the use of a smart card or other object containing encoded identifying information.

What the signatory is: Arguably the most secure of the three approval methods, approval here relies on some

sort of biometric identifier, some piece of physical and nonduplicable evidence of a person's identity. Such pieces of evidence include fingerprints, retinal vascular patterns, voice, and signature metrics, like speed, pressure, and stroke order (20).

Where electronic approval methods are implemented in the pharmaceutical industry, it will be of vital importance to comply with the FDA's Final Rule on Electronic Records and Electronic Signatures (21 CFR Part 11). In addition to broad guidance on the maintenance of the security and integrity of electronic records, the rule identifies specific requirements for the use of electronic signatures. First, signed records must indicate all of the following information: (1) the printed name of the signer; (2) the date and time of the signature; and (3) the meaning (e.g., review or approval). Second, the rule states that signatures executed to electronic records must be linked to the records in such a way that they cannot be excised, copied, or transferred to falsify an electronic record. Third, the rule establishes requirements around the uniqueness of electronic signatures to individuals within an organization and the controls that must be maintained to ensure that electronic signatures are used only by their genuine owners. Finally, and perhaps most importantly, 21 CFR Part 11 clarifies the necessity of notifying the users of electronic signatures that their electronic signatures are intended to be the legally binding equivalent of traditional handwritten signatures (2). The details of the rule surrounding electronic records and signatures are treated in greater detail later in this article

Security requirements: Protecting the corporate assets

Information and its knowledge base are the pharmaceutical company's most important asset after its people. The corporation's document management systems will either protect this asset or expose it to risk. Integrity of the information and assurance that the data were protected from fraudulent manipulation are at the heart of the new regulations (2) on controls for electronic records management systems. Technology has rationalized secure access to documents at each of the levels outlined in the schema of the paper-based file room. These levels range from broad to specific access privileges and are defined by (a) user login name (user security), (b) the user's affiliation with a group (group security), and (c) document status. The permissions associated with a given level of access entail those of all the more restrictive levels. For any user or group of users, the hierarchy of permissions is NONE, BROWSE, READ, WRITE, EDIT, DELETE, ALL.

Corporate network security: At the broadest level, access to the electronic file room must be monitored in the

same way as access to the physical file room. A firewall is the equivalent of security guards at the entrance to the building. Corporate firewalls are barriers that exist between an enterprise's computer networks, or intranet, and any external network. Generally, firewalls filter inbound and outbound data, provide or manage public access to requested locations, deny all services except those explicitly permitted by the system administrator, log traffic and activity through the firewall, and activate alarms as prowlers are detected (21).

Database security: At the level of the EDMS application, access is governed by unique user ID and password combinations. Here, database security serves as the guard at the door who requests to see your badge before allowing entry. The system administrator maintains an updated register of valid IDs and passwords for gaining access to the system linked, typically, to the current list of employees maintained by human resources (9).

Folder security: As with our brick and mortar analog, entrance to the file room does not grant you free access to all the holdings. A folder may be accessible to a specific class of user. User permissions over folders are typically limited to NONE, BROWSE, or READ. The ability to CREATE folders is typically the restricted province of the EDMS administrators.

File security: While it may be that a specific class of user has access to the entire contents of a folder, it may just as well occur that members of that class have access to all documents in the folder with some exception. For example, Human Resources employees may have access to documents containing the terms of employment for all employees except those in Human Resources itself. Security must be applied to these particular documents in the EDMS such that they cannot be viewed by Human Resources personnel.

Version security: In the paper world, archival documents held in a file room are in some sense final drafts. Security for a product document must be determined by its status. The electronic document management environment in which documents are managed across their entire life cycle by its very nature allows for the inclusion of draft materials. So, in addition to permitting or disallowing the viewing of the final version of a file, the electronic world must consider and secure access to draft versions. Usually, only authors, editors, and reviewers of files have access to the drafts before they are finalized. Once files are promoted to final status, this version is then promulgated to a broader readership. The draft versions, by contrast, may continue to be accessible by the authors, or may be locked or purged from the system.

Disaster recovery

Any treatment of security in the context of document management would be remiss if it did not mention audit trails and disaster recovery.

The system must maintain a log of document creation, modification, or deletion. The automated log includes information about the document that was affected, the time at which the event occurred, and the user who caused the event (2).

Disasters include the full range of unplanned catastrophes, from internal or external sabotage to the extreme forces of nature, like fires, tornadoes, and earthquakes that do real damage to a corporation's physical assets. Each of these occurrences presents a serious risk to an enterprise's profitability and viability. It is, therefore, essential that disaster recovery plans be well-conceived and fully supported by management.

Retention requirements: Storage and deletion

In keeping with the dictum that an EDMS should enable management of files across the entire document lifecycle, the system should automate retention schedules. The system should calculate scheduled document expiry based on business rules that map to system file categories. The system should then be programmed to notify document owners, usually at some predefined interval prior to actual destruction, as a final check on extenuating business needs for extending retention. Business rules based on regulatory and statutory requirements can be built into the system's automatic monitoring and retention/deletion functionality. For a comprehensive discussion of storage media, see Pollnow (22).

Scheduled retirement of documents is especially critical in the pharmaceutical industry, where corporations are routinely subject to audits by the regulatory authorities or to discovery in litigation. In such cases, retention of draft documents and other aged files often unnecessarily increases the company's liability exposure. Although administered centrally, retention programs ideally devise a mechanism for notifying document owners prior to destruction, alienation, or transfer, as the document's owner may know of compelling business or legal reasons to delay the destruction of the document (23, 24). An EDMS allows an enterprise to automate and rationalize all aspects of the retention program, including scheduling, notification, and retirement.

The EDMS Toolbox

An electronic document management system is a configuration of design tools, data capture tools,

messaging systems, repository databases, portals, and intra-/internetwork distribution and transfer options. There is no one magic bullet or single system that will provide solutions to the industry's document or knowledge management needs. With the almost daily introduction of new products, the best return on investment in technologies must be built on the principles of open architecture, best of breed products, and scalability. Designing, building, and constantly refining the corporate "digital nervous system" (18) is part of the cost of doing business in the paperless environment. In the next section we present an overview of key developments that undoubtedly will continue to redefine and reshape this complex and fluid corporate nervous system.

THE EMERGING PARADIGM

The transition from the paper environment to the early electronic environment was direct and intuitive. New computing models and technologies, however, are raising questions about the validity of this paradigm for complex information capture, access, and retention. In the current technology environment, forms, documents, data are not frozen, but dynamic and interactive. Communications and collaborations are as frequently machine to machine exchanges as direct human interactions.

It appears that in the rapidly evolving world of computing and communications (8, 25) the medium is indeed as important as the message. It is now possible to separate data and information from any document structure and technical platform. Whereas a document management system applies techniques of document locking, version control, and security to document objects, a component management system applies those same features to document fragments, or chunks, at a finer level of granularity. In other words, instead of checking out an entire document for editing, in a component management environment we may check out a single section, paragraph, or table. Much as the fundamental document objects that populate an EDMS can be combined in various ways as virtual documents, in a component management system document chunks form the basic elements and are "assembled" into whole documents. Component management is precisely the concept behind the regulatory search for a Common Technical Document (26).

The technology that enables both the creation of documents and the repurposing and redistribution of their content is XML, eXtensible Markup Language

(27). In terms of paperless documentation systems, XML signals a move from whole document management to component, or content, management. XML is a meta-language for describing languages that represent the content of a document. It is a subset of the Standard Generalized Markup Language (SGML), ISO Standard 8879, which has been around since 1986. SGML was devised as a means to create portable documents that are independent of any specific hardware or software.

HTML, which is also a subset of SGML, was developed as a means of transmitting hypertext documents over a network and specifies how a document should be displayed in a Web browser. HTML, however, describes neither the information content of a document nor its manner of organization. XML precisely fills this void by making use of tags and attributes to extend, validate, and unambiguously structure the content of a document.

Instead of viewing documents in an information system as passive objects to be served up to a human for reading, the SGML/XML paradigm regards them as active communications that can be parsed and manipulated by a computer. As such, they are data structures that can be used by computers rather than loose agglomerations of words, which can only be read by a human who comprehends the underlying grammar. XML's capacity to describe the content of a document as well as its organization makes it the ideal language for communication among both humans and machines. By encoding information in a format or tags that can be digested by both human and computational agents, XML is poised to become the true *lingua franca* of the Web in which both humans and silicon are initiators, brokers, and processors of transactions. To achieve this genuinely seamless communication, XML rethinks the very nature of documents themselves.

The usefulness of XML tags for structuring data presupposes the existence of a set of rules, or grammar, for their application. Such a grammar is embedded in either a Document Type Definition (DTD) or schema, both of which are defined by the XML author. A DTD is a set of syntax rules for tags. It establishes what tags may be used in a document, what attributes they have, and whether or not they can be nested inside other tags. Typically a DTD is maintained separately from a given XML document, though it can be part of it as well. Unlike HTML, which has a single DTD, XML supports as many user-defined DTDs as there are ways to structure information—thus, the extensibility. And also the danger. DTD's and, hence, XML are only as useful as the agreed upon standards that are used to implement them. The pharmaceutical industry stands to gain a great deal to the extent that it can establish and sustain extensive cross-corporation and FDA collab-

oration in the development of standard XML tags for its key documents. Should the industry fail to marshal a truly collaborative effort, it will have gained far less, being left instead with unique and peculiar DTDs and islands of XML that will exact a considerable cost to translate and maintain

Schemas are a newer development on the XML landscape. Like a DTD, a schema supplies the rules for building a document and indicates what tags may be used, what their attributes are, and how they relate to one another. Unlike a DTD, however, a schema has an additional level of specificity in that it can define data types. For example, a DTD might have a tag designated as `<DOSE>`, the content of which might be either numerical or a character string. A schema, by contrast, could ensure that the value entered was a number. This is clearly an appealing feature for the pharmaceutical industry, especially in the case of information exchange between databases or other applications making use of rigidly defined data types.

At the time of this writing, however, it still remains unclear whether schemas will overtake DTDs as the fundamental means of modeling XML documents.

XML structures document content but leaves presentation and formatting to other tools. The primary tool used for the job is now XSL, eXtensible Stylesheet Language. XSL consists of two parts: (1) a language for transforming XML documents and (2) an XML document for specifying formats. XSL allows users to process an XML document and dynamically render it to any number of formats. HTML, ASCII text, PDF, WML (wireless markup language) and XML itself are among the formats supported by the current technology.

XSL takes advantage of the intelligence built into the XML document to present its components in flexible ways. Thus, XSL does not merely apply style to the XML data; rather it evaluates, rearranges, and reassembles it. In fact, XSL permits multiple passes over an XML document so that information that appears once in the XML source can be presented multiple times in different formats within the same presentation. XSL, then, provides us with more than just an eye-catching rendition of XML data; it enables XML to realize its potential as flexible source information that can be created once but modified and presented infinitely many times. The application of this technology to the preparation and submission of information to multiple regulatory authorities is obvious.

Traditional paper models focused on discrete documents, file cabinets, and signature accountability. Setting aside the ability to commit fraud in any environment, the paper trail was clearly traceable from a physical file cabinet in the custody of a records manager responsible for

a uniform indexing scheme to the data owner through the signature on the document. The computer network trail, on the contrary, runs through multiple virtual file cabinets under multiple ownership, custody, and indexing schema with multiple signatures or access authorities applied at both the data and systems levels. Added to this is the complex multilayered architecture supporting the exchange and communication of the information (28). All of these elements are the document. The medium can no longer be separated from the message.

THE REGULATORY ENVIRONMENT: EFFECT OF LEGISLATION ON TRADITIONAL AND EMERGING MODELS

Developments in paperless documentation systems for the pharmaceutical industry are intimately linked to regulatory developments. That "there is no alternative to moving towards complete electronic record keeping" is acknowledged by industry and regulators (29,30). The most documented environment in pharmaceutical industry is unquestionably the manufacturing segment. As early as 1983, FDA issued guidelines on the inspection of computerized systems used in drug manufacturing (31). In this environment, where there is no evidentiary trail to support either the compliance or integrity of claims and, where there is no documentation of data, messaging, transactions, actions, criteria applied, historical experience, audit experience, or staff experience and training, the event, action, collaboration, or data itself are considered nonexistent. Repeatedly and often, FDA officials have stated, "If it is not documented, it did not happen." FDA modeled the requirements and standards of the Final Rule on Electronic Records and Signatures (Part 11) on the GCMR regulations (32). The agency acknowledges that most predicate regulations, however, were written without contemplating the use of any technology other than paper (2). (Preamble Comment XVI.A, p.13462)

Basic differences between the manufacturing environment and other segments of the pharmaceutical industry, particularly the clinical research environment, pose additional special difficulties for industry and regulators in complying with and applying standards to the electronic management of data and documents. In the manufacturing environment, documentation of processes and results is fairly self-contained within a single location or plant. There is typically a single cohesive business culture focused on common deliverables where individual business units are relatively seamlessly integrated. At the other extreme, in the clinical research segment of the

industry, documentation of processes and results is spread across multiple locations (e.g., investigational sites, CRO facilities, laboratories, sponsor offices). There are multiple business cultures, each with distinct deliverables (e.g., research facilities, consultant services, data management groups, marketing departments, finance). These multiple cultures and business units are not typically well integrated by a paper or any other technology platform.

There have been four pivotal legislative developments between 1995 and 2000 impacting the pharmaceutical industry:

1. *FDA Final Rule on Electronic Records and Electronic Signatures* (effective August 20, 1997): This is a permissive regulation allowing any FDA-regulated industry to maintain paperless documentation systems that will be considered the legal equivalent of paper records and record keeping systems.
2. *ICH Recommendations for Electronic Standards for the Transfer of Regulatory Information (ESTRI)* (effective March and July 1997): This agreement by member states defines open nonproprietary international standards for electronic communications and the transfer of data and documents between industry and regulatory authorities.
3. *Government Paperwork Elimination Act, Title XVII of Pub.L. 105-277* (effective October 21, 1998): This is a U.S. law requiring federal agencies to be prepared to accept by 2003 electronic information from persons required to maintain, disclose, or submit information to the U.S. government.
4. *Electronic Signatures in Global and National Commerce Act* (effective October 1, 2000): Again, this is a U.S. law giving electronic signatures and electronically signed documents in commercial transactions the same legal status as handwritten signatures applied to paper documents.

The latter two laws, although specifically United States federal regulations, will impact all e-commerce transactions because of the importance of the U.S. economy in the world marketplace. U.S. industries will seek the competitive edge advantage provided by this legislation.

Regulatory authorities are fully aware of the complexities that the new, rapidly evolving computer environment poses for their oversight responsibilities. Both FDA and ICH wish to avoid rapid obsolescence by crafting regulations and guidelines based on open nonproprietary standards and generic tools such as Adobe Acrobat's free portable document format (PDF) codes and reader application. The ICH ESTRI Gateway agreement is the first step in attempting to define a platform independent environment.

Final Rule on Electronic Records and Electronic Signatures

FDA's Final Rule on Electronic Records and Electronic Signatures (the Final Rule, Part 11) requires special discussion since it is the most comprehensive regulation to date on applying computer technologies to regulated industry (33). The rule itself is contained on two Space consumption pages. The most important part of the rule for the pharmaceutical industry is, arguably, the Preamble, which comprises 34 pages of discussion on how and why the FDA made its decisions on the requirements it would enforce. The preambles to both the proposed rule making and the final rule making detail current regulatory thinking on and compliance concerns with paperless documentation systems (34).

Scope

The initial announcement of the proposed rule referred to the regulations as an electronic signature rule. By the time of publication of the Final Rule in the Federal Register (62 FR 13430, March 20, 1997) (2), the title had been expanded to "Electronic Records; Electronic Signatures." FDA rejected comments that would have limited the scope of the rule to signature authority and manifestation issues or to those records only that are required to be signed, witnessed, or initialed. The agency's rationale was that the "reliability and trustworthiness of the electronic signature depends in large measure on the reliability of the underlying electronic record" and that electronic records need to be reliable, trustworthy, and compatible with FDA's mandate to protect the public health "regardless of whether they are signed" (2). (Preamble Comment 26, p.13438) Therefore, regulation, in the agency's opinion, was required for electronic record keeping per se. By March of 1997, the regulatory authorities were fully aware of the power of the new computing and networking technologies and the communications explosions fostered by the internet and wireless possibilities.

Part 11 defines records management as the "creation, signing, modification, storage, access, and retrieval" of records and the software and hardware platforms used in these processes. This regulation applies to any documentation required by an FDA "predicate rule." The Authorities cited for the rule are Secs. 201–903 of the Federal Food, Drug, and Cosmetic Act (21 U.S.C. 321–393); Sec. 351 of the Public Health Service Act (42 U.S.C. 262)]. For example, 21 CFR 820.70 requires documentation of process and production controls in quality systems for medical devices. This is a predicate rule. If any of this documentation is created, signed, modified, stored, accessed, or retrieved electronically, the requirements of

Part 11 apply to the documentation and the hardware and software supporting it.

Applicability

There is a caveat to the application of Part 11. As noted, it is a permissive rule. Industry has the "option" of compliance. However, if a company currently uses any electronic systems to create, sign, modify, store, access, or retrieve records, it is presumed by the law that they have elected to follow the regulations and comply with the standards. Consequently, the company is subject to FDA enforcement of the rule under the food and drug regulations. If a company elects not to comply with the regulation, it must revert to all paper systems. No electronic systems are "grandfathered" under the Final Rule. Continued reliance on current electronic systems for any one of the electronic records management activities requires compliance with the requirements of Part 11 for security and controls (2). (Preamble Comment XVI.C.1, p. 13463)

Key issues

It is important for the industry to understand FDA's rationale in establishing these regulations, if appropriate and reasonable compliance policies and procedures are to be implemented. Any industry interpretation of the rule should be based on a thorough understanding of the preamble discussion of the final regulation (34). FDA's concern to protect the public health translates into four major issues addressed by the Final Rule: identification and authentication of data and source; system confidentiality and security; accountability for signing a document; and enforcement.

Identification and authentication of data and data source (audit trail): The ability to verify the integrity of records and to trace accountability for creation and modification of data are probably the most significant concerns of the FDA in relation to their ability to protect the public health and hold individuals and corporations accountable.

There must be a system-generated time-stamped audit trail, created independently of the operator of a system, for any access to, modification of, or deletion of records or the audit trail itself. This audit trail is intended to enable detection of record and signature falsifications and to provide an evidentiary trail in the event of falsification (2). (Preamble Comments 72–74)

Confidentiality and security (controls): FDA recognized that deliberate intent to commit fraud is very difficult to prevent (2). (Preamble Comment 7, p. 13433) Acknowledging this, the agency defined system control requirements at the operational, network, and device levels

“to ensure that representations of database information have been generated in a manner that does not distort data or hide non-compliant or otherwise bad information, and that database elements themselves have not been altered so as to distort truth or falsify a record.”

Requirements for controls are based on definition of “closed” or “open” system. Under these definitions there is no direct correlation between, for example, using a public phone line and an “open” system. Compliance with “closed” versus “open” standards is determined by how access rights to the data or documents are established and controlled by the owner(s) of this information. A system is defined as “closed” if access to the system containing the records or data is under the control of person(s) responsible for the content of the records or data in the system. A system is defined as “open” if access to the system is not under the control of the person(s) responsible for the content of the records therein. For example, dial-in retrieval over a public phone is “closed” where the records being accessed are under the control of the persons responsible for their content, whereas storage of records on a third party system is “open” because access to the records themselves is under the control of the third party. Sections 11.10 and 11.30 of the Final Rule list, respectively, the control measures required for establishing a “closed” or “open” system.

Access must be protected through use of unique biometric or digital identification technologies. Examples of biometric technologies include voice or fingerprint recognition. Nonbiometric or digital signatures must consist of two distinct identification codes such as a network user ID and password. All access rights and system supplied identification codes must be periodically reviewed, updated, and/or changed by the data/document owner(s) and all personal identification codes, such as passwords, periodically changed by the user to ensure that unauthorized parties do not gain access to the data/records. Open systems require an additional level of encryption on the data/records to prevent fraudulent access.

Accountability for signing (repudiation and links): Signatures can represent different intent and responsibility and the electronic signing must capture this metadata. Electronic signatures can be executed using biometric or digital technologies or a hybrid of these. Part 11 provides minimal standards and generic technical recommendations for ensuring that e-signatures can be unquestionably linked to their owners, cannot be repudiated, and are executed with clearly evident intent and understanding of the act of signing (35). Whatever final configuration of signature technologies is used, it must enable the FDA “to hold people (i.e., the individual) to the commitment they make under their electronic signature” (2). (Preamble Comment 19, p. 13456)

In fact, when it was suggested that FDA also hold business entities accountable as well as individuals, the agency rejected the idea because business entities do not sign records, individuals do (2). (Preamble Comment 90, p. 13450) (23)

Legal enforcement (authority, inspection, implementation): Part 11 cites the complete Federal Food, Drug, and Cosmetic Act as its authority for this regulation and for the scope of its enforcement jurisdiction. FDA wants “enforceable” baseline standards (2) (Preamble Comment 2, p. 13432) and intends to inspect any component of an electronic records and signature system that has bearing on the trustworthiness and reliability of the record or signature (2) (Preamble Comments 33, p. 13489). The agency reserves the right to conduct inspections, even of sensitive security systems, if deemed necessary “to enforce the provisions of the act and related statutes” (2). (Preamble Comments 32, p. 13439) Supplemental guidelines will provide additional detail on the standards against which FDA inspectors would judge compliance (7). FDA will consider the need for additional legislative initiatives or criminal law reform if their experience with the current rule warrants (2). (Preamble Comment 90 and 124, p. 13450 and p. 13458, respectively) The first FDA 483 inspection reports on compliance issues with Part 11 began to appear in 1999. Mr. Paul Motisse, widely considered FDA’s architect of Part 11, was transferred to the inspection branch in the same year. As the agency gains experience and confidence with the new technologies, enforcement activities related to Part 11 will significantly increase.

Economic Impact

FDA asserts that the benefits of electronic record keeping in reduced review time and related business costs, such as space and rapid information access, will offset the costs of compliance with the rule (2). (Preamble Comment XVI.C.1, p. 13463) As industry and regulators enter the brave new paperless world, this remains to be verified.

It might be beneficial to discuss some of the current wisdom about the relative merits of paper-based and paperless documentation systems. Some of the claims about the outright superiority of electronic-based systems are perhaps overstated and highly context-dependent. Others probably have as much merit as their face value would seem to indicate. Table 1 provides a summary inventory of the pros and cons of the two models for document management.

Although a paper-based model for managing enterprise documentation appears to fall short of the promise for complex document management requirements, the

Table 1 Pros and cons of paper-based and electronic document management

Paradigm	Pros	Cons
Paper-based	Familiar Durable Transparent security model	Costly Inefficient searches Space consumption Inhibits leveraging of information assets Environmental impact Emphasis on separate repository function Audit management overhead
Digital	Space efficient Efficient searches Promotes leveraging of information assets Saves paper Integrates active file management and repository function Automates audit management	Durability of storage media Ever-changing technology standards High initial IT investment IT management overhead Environmental impact

paperless model is not without its own downside. Let us consider some of the issues in greater detail.

Cost

Paper-based systems are said to be costly. At roughly \$0.10 per sheet of paper, printing and filing between 5 and 10 million pages—perhaps a conservative yearly estimate for an organization of 2,000 employees—would cost between \$0.5 million and \$1 million (19). Are digital documentation systems any less expensive given the costs of purchasing, servicing, and operating the component hardware and software systems? The answer depends on the level of digitization of the system. In a hybrid system, where some paper is printed and scanned into an electronic filing system, the average costs of implementing and maintaining a document indexing and scanning solution is \$0.50 per page and ranges between \$0.20 and \$1.20 per page. It is difficult to assess the cost efficiencies of digitally based documentation systems for production and filing of documents. The full costs must include the initial investment in electronic systems and the outlays required to maintain them. It is no less incumbent on the pharmaceutical industry than any other e-commerce business to find a new measure, as precise as per page costs, for measuring its cost of doing business in the paperless environment (18).

Efficiency

Paper-based systems are increasingly considered inefficient. Relative to the file room scenario used to support the paper-based documentation model, it is hard to argue with the very real efficiencies afforded by the ability to search

vast and disparately located document repositories electronically. In a paper-based environment, the effort required just to retrieve documents has been estimated to be on the order of 4–7 hours per week per person (19). This does not include the time required to travel physically from one's office to a file room, walk the aisles of the archives, peruse the shelves and folders, and finally to browse the file itself for the relevant passage. In a 2,000 person organization with 250 working days a year, this totals 50,000 to 87,500 person days per year across the organization.

By contrast, search and retrieval in an electronic environment is said to save 10 to 20 percent of the total individual work effort required, not just the effort required to retrieve documents. In one year, an electronic system would save this company 50,000 to 100,000 person-days of effort, potentially all the time spent searching in a paper-based system and more (19). If network downtime is equivalent to employee downtime, comparison between the two modes of search and retrieval appears absurd (36).

Space consumption

If the average enterprise professional creates approximately 500 documents a year, accumulates around 200–300 more from external sources, and an average document is from 5 to 10 pages in length, then an organization of 2,000 employees generates around 1 million documents containing some 5–10 million pages (19). Add the external documents and the organization contends with another 2 to 6 million pages. Continuing with the multiplication exercise, a ream of

paper is about 2 inches thick, so given the above volumes an enterprise must find space to accommodate anywhere from 2,333 to 5,333 stacked feet of $8\frac{1}{2}$ by 11 inch paper, or between 1515 and 3463 cubic feet. In raw terms, the upper end of this volume will fit into a room measuring 35' by 10' by 10'. When one considers that this does not take into account the folders, shelves, and aisle space required to intelligently store and navigate the documents, and that this is merely the volume of documentation encountered in a *single* year, entire floors of city-block-wide buildings can very rapidly disappear in an effort to retain it all.

Ten million pages requires about 500 gigabytes of disk storage space. The space occupied by the servers and disk drives for a decade worth of documents would probably not exceed the 35' by 10' room cited above as the minimum requirements for packing a year's worth of documents. Standard dimensions for 30-gigabyte hard drives on the market today are roughly 2.75" by 4" by less than half an inch in height. Simplifying somewhat, two hundred such drives, stacked one atop the other, would occupy less than 9 linear feet and only half a cubic foot. Even with the overhead required by server hardware, monitors, and the like, the space savings won by electronic storage of enterprise documentation are considerable. However, in the digital world, the cost of bandwidth is a major factor in "digitalizing" the workplace in both large and small corporate budgets (37).

Environmental impact

The high-tech digital alternative must be vastly more "green" by these measures. Yet, it is not immediately clear that the paperless documentation system is as environmentally friendly in practice. In general, the high-tech industry is pretty dirty. Chip manufacturing involves hundreds of chemicals (e.g., acids, cyanide compounds, silicon tetrachloride), many of them toxic or carcinogenic alone and, perhaps, more so in combination (39–42). The industry also wastes prodigious amounts of water, and pollutes both air and water (43). The reality of Moore's Law, which roughly states that the power of computer technology (i.e., the miniaturization and data density of transistors and microchips) doubles every 18 months, has landfills overflowing with obsolescent machines and components (44). Consider also the power required to operate electronic document management systems. The presumed environmental advantages, which *prima facie* seem obvious, are in fact not so clearcut.

Current wisdom maintains that paperless documentation systems are more environmentally friendly than paper-based systems. If an enterprise implements a system in which documents are generated, stored, and retrieved electronically, it can conceivably preserve the number of

trees corresponding to the number of sheets of paper it would otherwise generate. In a 2,000 person organization, which produces 10 million documents, that amounts to 850 trees a year (19). Typical offices produced 100 lbs of paper per head in 1975. In the still burgeoning paperless office, they produce more than 200 (1). One might argue that the paper industry exacts as in an even more terrible toll in terms of sulfur dioxide, resinous acid effluent (38).

Storage and durability

With respect to the most fundamental security issues (i.e., a document's persistence through time), it is rather easy to assume that digitized information, with its tight controls, rigid architecture and underlying ingenuity, must somehow offer greater long-term protection of stored document assets. To do so, however, is both to underestimate the durability of paper as a storage medium and overestimate that of digital media and the dominance of any single technology platform capable of reading digital media formats. Ineluctable technological obsolescence is perhaps the greatest threat to the preservation of electronic documents and data (45–48).

The above considerations have direct bearing on the presumed economic impact of regulations for the pharmaceutical industry on electronic record keeping systems. The pharmaceutical industry is, in fact, faced with a complex, costly development and implementation project once it heads down the road of electronic record management within the regulated parameters of Part 11. These costs and the attendant legal issues will increase within a fully digitalized, paperless environment. The key to a return on investment for the industry will be its ability to integrate and strategically plan technical implementations across multiple business divisions (49, 50).

CONCLUSIONS

Digital tools provide instantaneous distributed access to original experience. In a paperless world, one that is mobile, wireless, and extremely portable, customers seek data versus documents (37). Documents have become data embedded in inseparable multiple layered architectures (28). Technological and economic forces have essentially redefined document formats and purposes. The goal is more and more to preserve or re-create the immediacy of a communicative act, just-in-time delivery, real-time updates

"Document objects" have, in addition to text, come to include databases/spreadsheets, graphics, images, video, audio, web sites. What a document used to be is now a

small part of documentation—audit trails, metadata, etc.—where documentation of immediate experience is immediately available to third parties. Documentation is now an environment of dynamic interactive support as opposed to the static support of imaged paper.

The pharmaceutical industry is traditionally document driven. The technology exists currently, however, for conducting research, manufacturing product, and promoting prescription drugs in a totally paperless environment. Several years ago the CEO of Boeing Corporation threw down a gauntlet to the aerospace industry. He asked what would happen if they designed and built a plane without any paper, and succeeded in doing it. In 1999, Bill Gates laid out the business case (18) for conducting any business as e-commerce. Both individuals were visionaries in understanding the possibilities of the new information technologies and translating them into a competitive edge for their industries.

Within the clinical research arena, the CRF, for example, will become a metaphor for a complex, multidimensional process of data collection providing an on-line interactive profile of the subject's experience and data. New technologies such as voice recognition, digital medical imaging, targeted drug discovery techniques, revolutions in computing design and power (8, 25) and the genome project (51, 52) are redefining for both industry and regulators how we capture and manage subject-specific data in a meaningful profile of an individual subject's experience. These same technologies, especially as they enable the discovery, mapping, and repeated use of genetic information, will redefine the execution and need to monitor informed consent rights for subjects. The protocol itself will be redefined as a set of "edit checks," access rights, system administration rules, and metadata structures controlling the on-line collection, verification, and analysis of data.

How should the pharmaceutical industry apply these possibilities to drug development and marketing? Fully "digitalizing" clinical research, for example, would revolutionize the industry's concepts of document, data, and regulatory review. It is no less impossible to apply Boeing's challenge to the manufacturing sector. Of all the areas in the industry, marketing, which is built on messaging and interactive communications, has innumerable models and other industry experience with e-commerce. Within the next five years, the industry needs to challenge its traditional thinking on pharmaceutical documentation and thoroughly explore the possibilities and issues involved in abandoning traditional paper paradigms for a fully digital environment (49, 53).

How can the regulatory agencies respond to this new environment in keeping with their legal mandate to protect

the public health? The regulators have begun to tackle some of the issues in the Final Rule on Electronic Records (2) and the ICH ESTRI agreement (5). This legislation is merely the tip of a large, complex "iceberg" of law, public policy, and oversight techniques. Traditional documentation will become a metaphor for complex, integrated data capture and repository systems linked to enable dynamic "on-the-fly" profiling, analysis, and reporting of research and discovery results almost simultaneously with the direct research experience. The pharmaceutical industry, its regulators, and the consuming public have entered into a brand new collaborative world.

Glossary of Technical Terms

A comprehensive listing and definition of terms is available at <http://www.webopedia.com>

PARTICLE-SIZE CHARACTERIZATION

Brian H. Kaye

Laurentian University, Sudbury, Ontario, Canada

SAMPLING PROCEDURES

The subject of powder sampling has been addressed extensively in standard reference books. Several companies sell sampling equipment for installation in industrial systems (1–7). Even when the sample received by the laboratory is a representative sample, the analyst still faces the difficult task of taking a small subsample from the powder supplied. It has been shown that one of the most efficient devices for taking a subsample of the powder is known as the spinning riffler, shown in Fig. 1a. It consists of a ring of containers that rotates under the powder supply. The total powder supply is processed using this instrument. It has been shown that to obtain a representative sample, the time of powder flow through the apparatus divided by the time of rotation of the ring of containers should be a large number (4, 7). Difficulties arise using such devices with very fine powders because air currents caused by the rotation of the system can blow the fines away. Furthermore, if the powder is cohesive (sticky), the powder flow through the funnel can be impeded. In some situations, the flow properties of the powder can be modified by adding a silica flow agent, provided this does not interfere with the size characterization procedures used subsequent to the sampling procedure (8).

Another approach to the sampling of powders has been developed by Kaye and coworkers. In this procedure, the powder is thoroughly mixed in such a way that any sample taken at random is a representative sample (9, 10). The equipment used in this technique is shown in Fig. 1c. The mixing chamber is placed in a rotating drum lined with dimpled foam. The foam serves two purposes: first, it promotes quiet tumbling of the chamber, and second, it accentuates the lifting power of the rotating drum so that it lifts the partially filled chamber up the wall of the drum until it tumbles chaotically to a new position of equilibrium before it is again lifted up for the next tumble. The chaotic tumbling of the mixing chamber creates ideal conditions for powder mixing, and short mixing times have proved to be efficient in mixing the ingredients (11). At the end of the tumbling procedure, a small sampling cup attached to the lid of the mixing chamber is used to retrieve a representative sample. The tumbling chamber

can have various geometric shapes, and provided that dimpled foam is used, even a common laboratory jar can be tumbled. Efficiency of mixing is reduced if the jar is more than half-full, because this imposes restrictions on the free, random movement of the powder in the chamber. It is recommended that this type of device be used to homogenize any powder sample before using a subsample in an experimental investigation, if the sample has been kept for some time or has been poured in a laboratory environment. Powder segregation mechanisms are far more widespread in the laboratory than generally known (12, 13).

In Fig. 2, a new pneumatic sampler developed by Kaye and coworkers is shown. This instrument has the advantage that one can take a sample of any specified size by changing the position of the sintered frit in the central tube that is used when the sample is drawn into the equipment. Lubricating air provided through both concentric tubes enables the sampling device to be moved to a particular location within a powder. When the sampling location is reached, the airflow to the center tube is reversed to draw in the desired sample (14).

For sampling an aerosol system, a cascade impactor is used to fractionate the aerosol into various size ranges. A full discussion of these instruments has been reported by Kaye (1). Aerosols can also be sampled through various filter systems for subsequent examination by image analysis procedures. If the aim of the sampling process is to generate a deposit that can be examined through a microscope with an imaging system, surface filters, such as the Nucleopore filter and similar polycarbonate filters, are available in various pore sizes for filtering aerosols (15–17). The traditional paper filter is described technically as a depth filter. Although depth filters can sometimes be rendered transparent by using immersion oil, it is normally difficult to view the fine particles on depth filters because they penetrate into the pore structure of the filter (18).

The study of the size distributions of therapeutic aerosols creates a very difficult sampling task for the specialist. Wherever possible, size characterization of an aerosol system should be carried out *in situ*, using diffractometers as discussed later.

SAMPLE PREPARATION

In many situations, a powder sample to be characterized has to be prepared in a specified format for the characterization procedure. Thus, the powder may have to be spread out on a glass slide before microscopic examination, or a suspension of the material may have to be prepared in an appropriate liquid or gas. The act of dispersing the powder to be studied can change its size distribution radically, and the procedure used to prepare the sample for characterization should allow for what is known as the operational integrity of the fine particles. Thus, if the powder is to be dispersed in water, the use of ultrasonics to disperse it in the liquid can result in the shattering of agglomerates that would normally persist throughout the manufacturing and usage processes.

In general, the technology used to disperse a powder before a characterization study should match the severity of

dispersion forces that the powder will experience in use. Alternatively, if ultrasonics is used to generate a well dispersed powder, the analytical procedure protocol should be defined rigorously to avoid variations from operator to operator. Dispersing agents are frequently used, and great caution should be exercised because they can alter the structure of the system in a fundamental manner (19).

SIZE CHARACTERIZATION OF FINE PARTICLES AND POWDERS

Direct Examination with Microscopes and Other Imaging Devices

Extensive pioneering fine particle characterization studies were carried out by Heywood and Hausner, respectively,

Fig. 2 The improved pneumatic lance is constructed from concentric tubes. Low-speed aeration from both tubes allows the lance to be inserted with minimum disturbance to the powder supply. Once the sampling location is reached, a high-speed flow is applied to the central tube to capture a sample below the filter or frit. a) Construction of the pneumatic sampler; b) process used to obtain a sample from a bulk of powder.

by examining images through microscopes and other imaging devices (20, 21). In these early works, the areas, or dimensions, of profiles were measured by direct comparison of the profile images with sets of reference circles engraved on what was known as an eye piece reticule (1). Recently, several sophisticated systems have been developed for computer-aided image analysis (1, 22).

The increased power of processing logic, available in modern computer-aided analysis systems, makes it possible to characterize the shape of fine particle profiles using Fourier analysis techniques and to describe

structures by means of fractal dimensions. The Fourier analysis techniques can be carried out in one or two dimensions (23). When exploring the structure of a profile in one-dimensional space by means of Fourier analysis, a reference point is located within the profile, and a geometric signature waveform is generated by rotating a vector at uniform angular velocity around the perimeter of the profile. The magnitude of the vector plotted against the angle of the vector generates the waveform. This waveform is subjected to Fourier analysis to generate a power spectrum of the various harmonics contributing to

the structure of the waveform. This technique is useful for rounded objects but generates complex information if there are deep convolutions or sharp edges on the profile. For such profiles, two-dimensional Fourier transforms can be generated by computer (23, 24).

A different procedure for describing the structure of rugged profiles has been developed from the theorems of fractal geometry (24–29). The basic concept used in fractal geometry is to add a fractional number to the topological dimension of a system to describe the space-filling ability of the system being described. Thus, in Fig. 3a, all the lines have a topological dimension of one. The fractional number added to this dimension creates the boundary fractal dimension of the line, a parameter that describes the ruggedness of the line. In Fig. 3b, the basic logic used to evaluate the fractal dimension of a profile of a powder grain by the equipaced method is shown. Polygons are constructed on a digitized form of the profile, a sequential set of x,y coordinates representing the profile, by pacing out a given number of steps around the profile. Polygons constructed in this way become perimeter estimates at the inspection resolution represented by the number of steps paced out along the profile. The perimeter estimate and the resolution are normalized with respect to the maximum projected length of the profile. To estimate the magnitude of the fractal dimension of the profile, the normalized values of the perimeter estimates are plotted against the normalized resolution, as indicated in Fig. 3c. This plot is known as a Richardson plot after a pioneer of the detailed studies of convoluted profiles such as these of islands (25, 26). The slope of the data lines on the Richardson plot represents the fractional number that has to be added to the topological dimension to describe a structure of the boundary. As with the profile studied in Fig. 3b, some fine particle profiles exhibit different fractal dimensions at different levels of inspection. Thus, in this profile, what is known as the structural boundary fractal dimension is revealed by the course resolution data, and what is known as the textural boundary fractal dimension is revealed at high-resolution inspection. The structural fractal dimension probably governs the packing and flow properties of a powder, whereas the texture governs the dissolution rate, adsorptive capacity, and chemical activity.

Because of the large amount of visual information imparted by an image of a fine particle, there has been a tendency to regard image analysis inspection as a fundamental method against which all others should be measured. The principal problem involved in the inspection of a system by image analysis is the difficulty of deciding what constitutes a separate and operationally functional fine particle. A failure to record the density of coverage of the surface used in a microscopic study of a

powder is a major source of uncertainty in the value of the reported data, because random juxtaposition of fine particles on a surface can make them appear as preexisting agglomerates (30).

Sieve Fractionation

Sieving is a widely used method for characterizing the range of grain sizes present in a powder. In this technique, a quantity of powder is separated into two fractions on a surface containing holes of a specified uniform size. The two main problems associated with sieve characterization are the difficulty of determining the point at which the fractionation process is complete and coping with the variation in sieve apertures present in new and worn sieves. For a discussion of see Refs. 1 and 22. The photomicrograph of a woven wire sieve surface in Fig. 4a illustrates the problems associated with the variations in sieve apertures. In Fig. 4b the data on the variation of the sieve apertures as characterized by various studies are plotted (31). The midpoint diameter of the trapezium created by the projected image of the woven wire surface provides the operational diameter of the sieve, and the size distribution of the apertures can be measured with the help of image-analysis techniques. The size distribution determined in this way can then be normalized by the nominal aperture of the sieve. It can be demonstrated from the data in Fig. 4b that the aperture distribution is Gaussian.

In an alternative technique, spherical glass beads are separated on the sieve, and when the remaining oversize beads are poured off of the sieve, the near mesh-sized beads trapped in the mesh are removed by inverting the sieve and giving it a sharp rap on a surface. The beads collected in this way are then sized. If an irregularly shaped powder is used in such an experiment, a typical set of grains trapped in the openings of the sieve allows one to determine the shape distribution of the profiles, as illustrated in Fig. 5. Electroformed sieves have a much narrower distribution of aperture sizes but are more fragile and expensive than woven wire sieves (1).

Sedimentation Techniques

Sedimentation procedures to evaluate particle size in terms of the equivalent spheres, which have the same settling speed in laminar flow conditions, are the basis of many techniques used to characterize fine particles. A suspension of fine particles is prepared, and their falling speed is determined with an immersed balance pan or by monitoring the settlement of the fine particles with the help of light or X-ray beams. The measured falling speeds of the fine

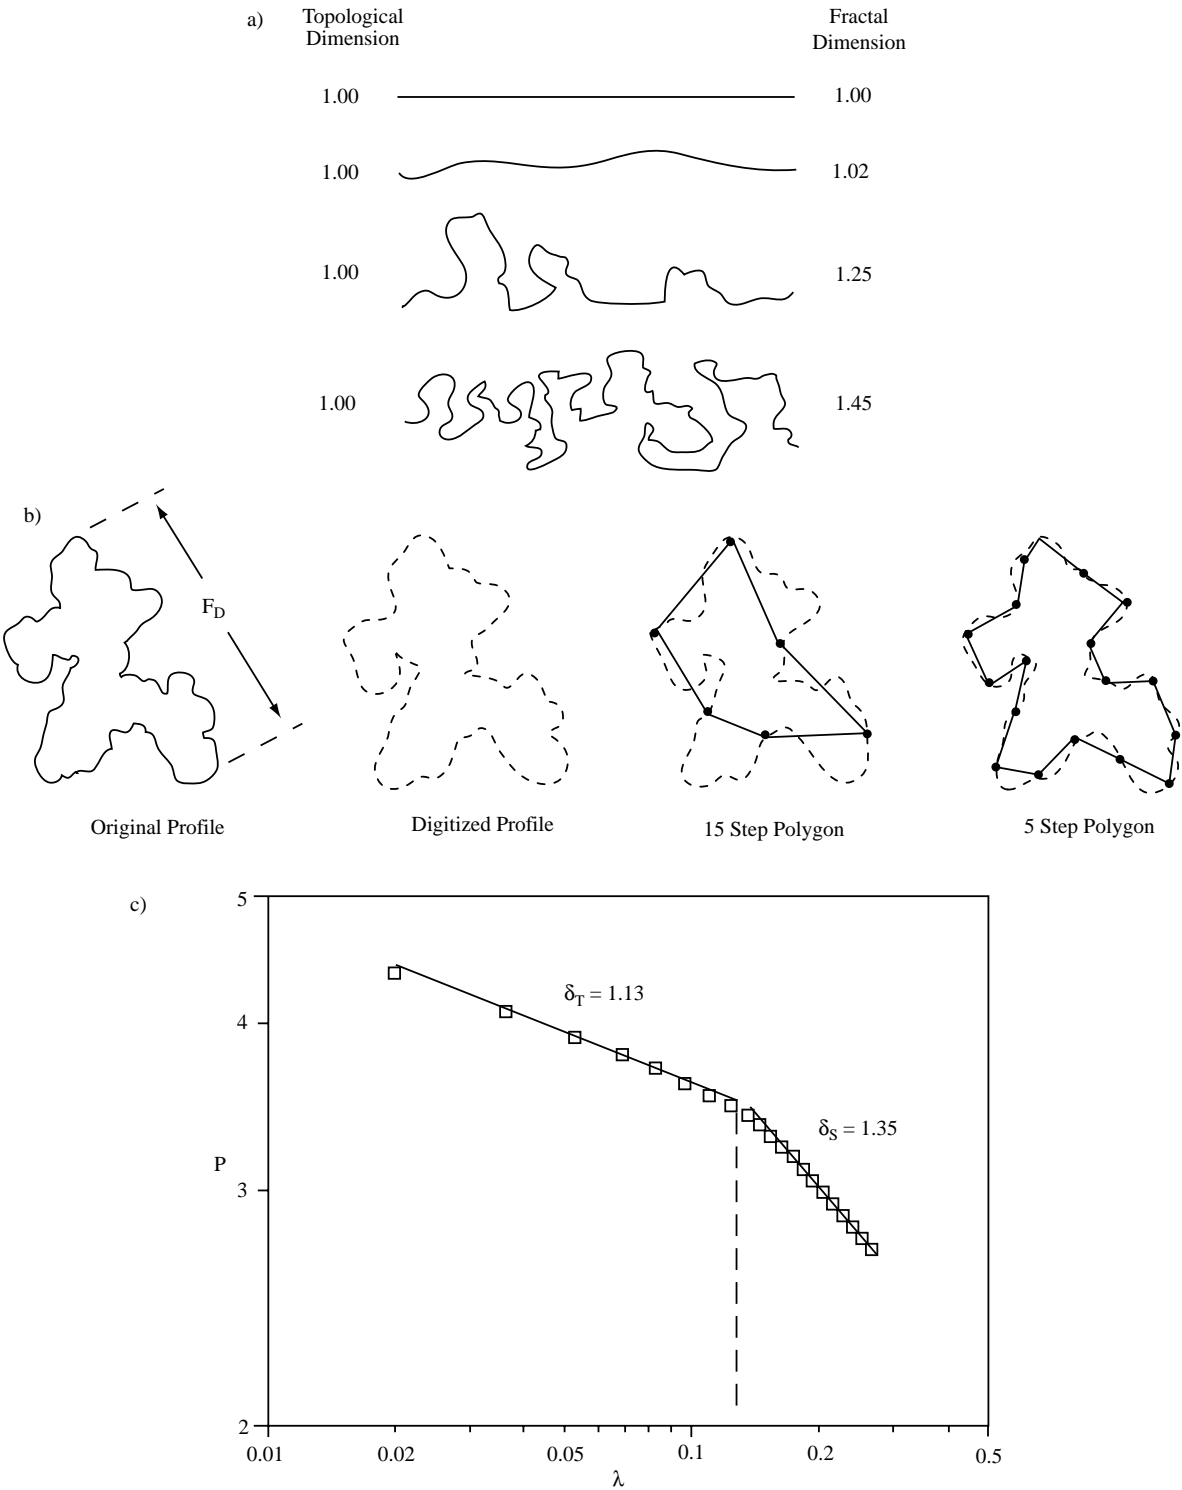

Fig. 3 Fractal dimensions can be used to evaluate the rugged structure of fine particles. a) Fractal dimensions used to describe the ruggedness of various lines; b) physical basis of the equipaced exploration technique for evaluating the fractal dimensions of rugged boundaries; c) data generated by the equipaced exploration technique for the profile of b; δ_S ; structural boundary fractal dimension; δ_T ; textural boundary fractal dimension.

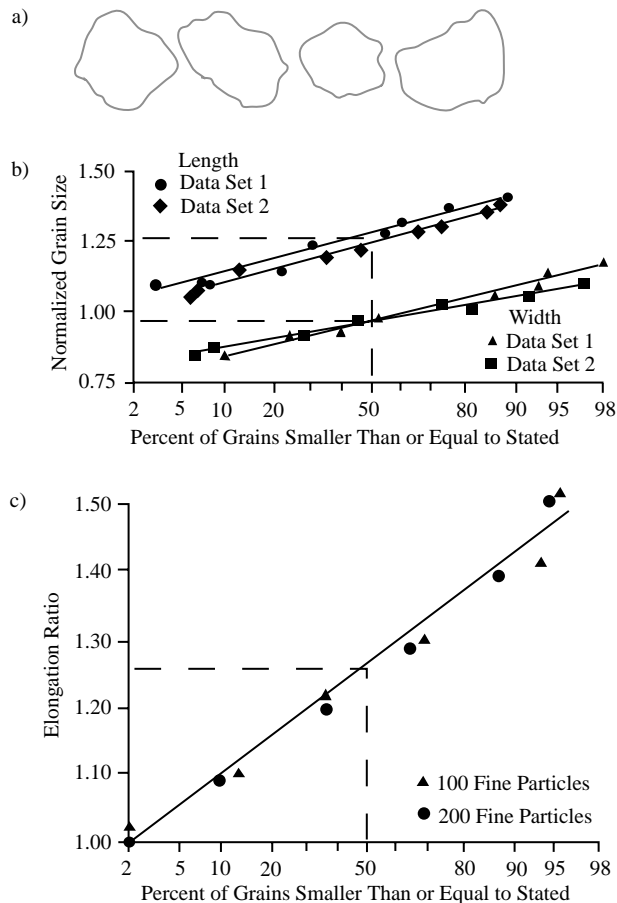

Fig. 5 When calibrating a sieve mesh with trapped irregularly shaped grains, a subset of powder grains is obtained that can be used to generate a shape description of the powder grains (31). a) Profiles of typical sand grain trapped in a sieve mesh; b) length and width distributions of sand grains trapped in a sieve mesh; c) elongation ratio (shape) distribution for sand grains trapped in a sieve mesh.

particles are inserted, along with the other appropriate parameters of the suspension, into Stokes' equation

$$d_s = \sqrt{\frac{18\eta t}{(\rho_p - \rho_L)gh}}$$

where d_s = Stokes diameter of the fine particle; η = viscosity of the liquid; g = acceleration due to gravity; h = distance through which the fall is timed; t = time required to fall the distance h ; ρ_p = density of the powder; and ρ_L = density of the liquid.

The configuration of the actual instrument used to measure the Stokes diameters of fine particles varies among instrument manufacturers (1, 22). Devices that

monitor the fine particle sedimentation with a light beam are known as photosedimentometers. Because of the difficulties of interpreting the concentration measurement of fine particles with diameters close to that of the wavelength of the light being used to monitor the dynamics of the suspension, some instruments use X-Ray beams to monitor the fine particle movements. Other instruments use centrifugal force to accelerate the settling dynamics of the suspended fine particles.

Sedimentation methods were the dominant size-characterization procedures in the 1950s and 1960s. In recent years, they have been replaced in the powder laboratory by the diffractometers. Diffractometers have the advantage of speed, but problems occur in the interpretation of the diffracted light signals. The X-ray-based sedimentometer manufactured by the Micromeritics Corporation, called the Sedigraph, is still widely used, partly because its use is written into some industrial standards governing size-characterization procedures (32, 33).

In recent years, disk centrifuges have been revived to characterize fine particles smaller than $1\ \mu\text{m}$, basically because of the work by Provder and coworkers in cooperation with Brookhaven Laboratories Ltd. (34).

Diffractometers

The advent of the laser has made the generation of diffraction patterns by a suspension of fine particles a relatively easy task. At the same time, the rapid development of computer-processing equipment and specialized photocells has made it possible to process the information in a group diffraction pattern to generate the particle size distribution of the fine particles in suspension. One of the first commercially available devices for generating size-distribution information from group diffraction patterns of a randomly dispersed array of fine particles was the CILAS device (Denver Autometrics, Inc., Boulder, CO) first developed in France to measure the size distribution of cement (35). Companies that have developed diffractometers do not divulge the structure of their software. The user of this equipment should be careful to obtain information on the data-processing protocol followed in any specific instrument to change the diffraction information into a size-distribution function. Some of the instruments assume a given distribution function and curve fit to accelerate the data processing. Sometimes such curve fitting can distort the data generated (36). Several manufacturers of these instruments provide extensive technical data on their performance, and the International Standard Organization is currently preparing a standard procedure for diffractometers. The laser

diffractometers are particularly useful for studying the size distributions of sprays and aerosol clouds (37–43).

Time-of-Flight Instruments

Another type of instrument that has been made possible by the availability of lasers is known as the time-of-flight instrument. Here, a narrow focused beam of laser light

explores an area of a suspension. The size of the particles in suspension is measured by the time it takes for a laser beam to pass across the profile of the fine particle. Sophisticated optical recording devices and electronic editors are used to generate the size distribution data from the information generated by the device.

An instrument developed and marketed by Galai Instruments (Haemek, Israel), sold in the United States for

Fig. 6 The Galai particle-size analyzer uses a laser beam and a rotating wedge prism to measure the size of fine particles by the length of time the fine particle blocks the light reaching the photodetector. a) Basic layout of the Galai instrument; b) the laser beam traces a circular path within the sample cell, and the logic of the instrument rejects any particles that are off-center or out of focus; c) the length of time that the laser beam is blocked is related to the size of the fine particle. (From Ref. 44.)

several years by the Brinkmann organization but now marketed directly by Galai Instruments, is shown in Fig. 6. A useful feature of this instrument is that as the fine particles are being characterized by the scanning laser beam, they are also imaged on a television screen in such a way that any agglomeration can be detected during the analysis. The logic of the Galai system allows the fine particle shape to be measured concurrently with size (44).

Another time-of-flight size analyzer is known as the LASENTECH (Bellevue, WA). This system is portable and has been suggested for use as an online monitor for fine particles moving in a system as well as in the laboratory (45). A different type of time-of-flight instrument is known as the Aerosizer (TSI, St. Paul, MN) (46). Here, the stream of aerosol fine particles is accelerated across a gap defined by two laser beams. The time of flight across this gap is measured from the light signals scattered from the two light beams, and an electronic editor ensures single occupancy for the measurement series. The larger fine particles are slow to accelerate across the gap, whereas the smallest move with the speed of the feed air jet. The system is calibrated using standard fine particles.

Another similar instrument is also manufactured by TSI. The basic system for measuring the aerodynamic

diameter of aerosol fine particles is shown in Fig. 7. Using this instrument, the velocity of a moving fine particle being accelerated across the inspection zone is measured with the Doppler shift in two beams that have a different directional reference to the moving airstream. From one perspective, the two lasers beams can be regarded as creating interference fringes, whereas the aerosol fine particle moving across the fringe system creates an oscillating signal that can be related to the fine particle size via calibration measurements. The fact that the instruments with which aerodynamic sizes are measured by the movement of the fine particles across crossed laser beams involves laser Doppler shifts is not immediately obvious from reading the trade literature of companies marketing this type of instrument. Indeed, in this class of instruments, the interpretive theory is complex, and the user is generally provided with a calibrated instrument to carry out the characterization studies of interest (46, 47).

Photon-Correlation Spectroscopy

Another instrument, in which the physics of the measurements are not immediately obvious to the outside observer, is part of a group of instruments variously referred to as photon correlation, dynamic light scattering,

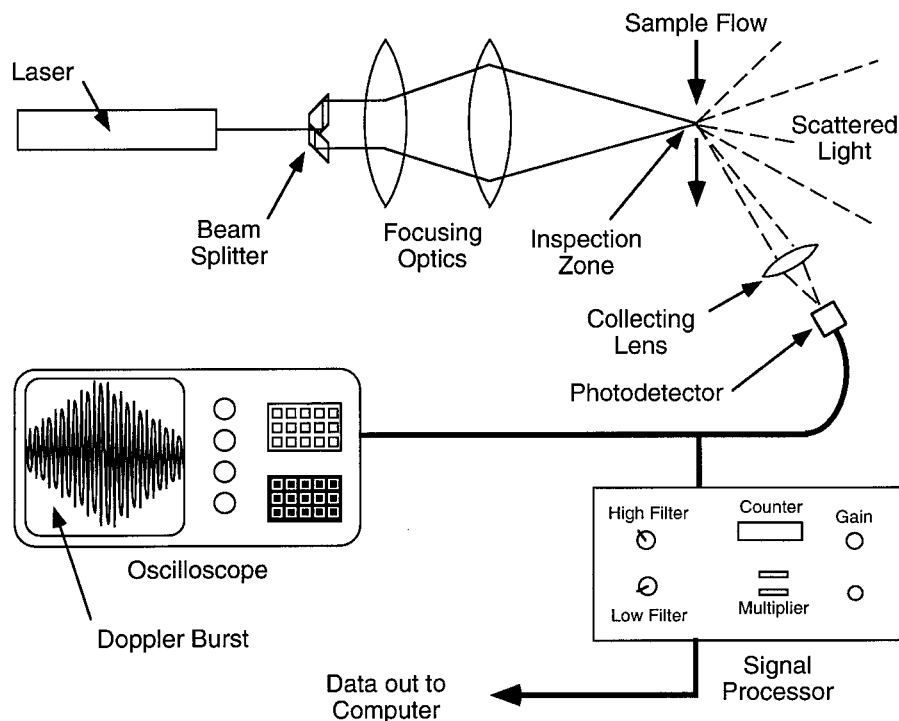

Fig. 7 A Doppler-shift procedure for measuring the aerodynamic size of aerosol fine particles is used by the TSI aerosol particle sizer. (Form Refs. 1 and 46.)

or quasielastic light scattering spectroscopes (often referred to as PCS, DLS, or QUELS). In this discussion, the term photon-correlation spectroscopy is used (48–51). Its physical basis is the monitoring of the Doppler shifts in reflected laser light created by the Brownian motion of submicron fine particles. In some cases, the technique can also be applied to fine particles of several microns in diameter. The equipment for actually measuring the Doppler shifts is relatively simple, but the overall expense is increased by the data-processing that is usually included. This instrument is useful for studying relatively simple size distributions such as latex suspensions. However, interpreting a wide range of sizes in suspension with this technique can involve complex data processing that, if carried out incorrectly, can generate confusing data (48, 50, 51).

Stream Counters

Another size characterization instrument group is known as stream counters, in which a stream of fine particles is passed through an inspection zone. The physical properties of the inspection zone are changed by the presence of the fine particles. The size of the fine particle is deduced from this change. In the Coulter counter, the fine particles to be characterized are placed in an electrolyte, and a stream of suspension is passed through an orifice between two electrodes as shown in Fig. 8 (52). The size of the fine particle is deduced from the measured resistance change between the electrodes.

Fig. 8 Schematic representation of the operation of the Coulter counter. (Form Ref. 52.)

A major problem with stream counters is the single occupancy of the fine particles in the inspection zone. Should there inadvertently be two fine particles in the orifice, they register as one large fine particle, and the counting of the smaller particles has a deficit of two. This type of error is referred to as primary count loss (the undercounting of the smaller fine particles) and secondary count gain (the false registering of larger fine particles owing to multiple occupancy of the zone). Normally, the analysis with this type of instrument is carried out in a series of increasing dilutions until further dilution does not affect the measured size distribution. A difficulty sometimes encountered with this method is the availability of a conducting fluid that does not interact with the fine particles to be inspected. Over the years, various sophisticated data-processing techniques have been used to allow for problems associated with the Coulter counter, for example, when the fine particles are too close to the walls of the orifice or have extreme shape (1, 22).

In another group of stream counters, the fine particles in the inspection zone are monitored with a light beam. Various models of this type of instrument have been developed to count fine particles in liquids; others are specialized for the counting of dust fine particles in the air (1, 22, 53–55).

Elutriators for Size-Characterization Studies and Fine-Powder Fractionation

Elutriators are a class of instruments that fractionate fine particles according to their size by manipulating them in a moving fluid. They are among the first devices used for measuring size distributions of powders by fractionating them into various size groups and weighing the amount of powder in each group. The Roller elutriator was widely used in the powder metals industry (1). In recent years, elutriators have tended to be displaced from common use by diffractometers and other optically based instruments. They are still extremely useful, however, for fractionating powders into different sizes to study the physical variations of properties with size. Thus, a drug powder can be fractionated into various sizes to study the dependence of the bioavailability of a drug on its particle size. Fig. 9 shows three basic types of elutriators for fractionating powders and studying aerosol fine particles. In the gravity elutriator shown in Fig. 9a, air or another suitable fluid is passed upward through powder placed on a filter. As the air moves up through the column, the velocity of the moving fluid can be adjusted to move all fine particles below a certain size from the elutriator body to a fines collector, which may be a filter or a cyclone. The size limit, defining the size of the fine particles remaining

Fig. 9 Elutriators can use gravity or centrifugal force to separate fine particles into undersize and oversize fractions. a) Gravity elutriator; b) Cyclone (centrifugal elutriator); c) Impactor. (From Ref. 1.)

in the elutriator, is called the cut size of the elutriator. Because it is difficult to control the movement of the fluid and because of turbulence, the cut size and the fractionating power of an elutriator are not precise. A microscope or other suitable device is needed to investigate the actual fractionation of the powder in a given elutriator.

Cyclones are widely used in industry to fractionate powders. The operation of a cyclone, which is in fact a centrifugal elutriator, is shown in Fig. 9b (56). The stream of fluid suspension containing the fine particles to be fractionated enters the top of the cylindrical body

tangentially. The fluid stream is made to spiral downward through the body of the cyclone until it can reverse its flow and leave through a pipe known as the vortex finder. As the feed stream spins around the body of the cyclone, the coarse particles in suspension are thrown to the wall by centrifugal force. At the wall, the coarser particles fall down into the conical bottom of the cyclone. The cut size of the cyclone, which determines how small the fine particles leaving through the vortex finder are, is determined by the dimensions of the cyclone and the velocity of the fluid stream. Small cyclones are widely used in occupational hygiene studies (56).

Another device for depositing fine particles from an airstream is the jet impactor, shown in Fig. 9c. The airstream containing the suspended particles is impinged onto a glass slide. As the airstream is forced to turn because of the slide under the jet, centrifugal force pushes the suspended fine particles onto the slide. The smallest fine particle, which is just deposited on the slide, is determined by the jet-slide configuration and the speed of the airstream moving through the equipment (1).

Giddings and coworkers have developed a series of cross-flow classifiers known as field-flow fractionation devices. The procedures, often referred to as FFF, are defined by Giddings (57) as: "a family of high resolution techniques capable of separating and characterizing materials in the macromolecular and colloidal range and beyond." Applications of FFF span a ten- to fifteen-fold mass range, extending from molecules under 1000 molecular weight to particles 100 microns in diameter. Particles as diverse as cells, subcellular particles, viruses, liposomes, protein aggregates, fly ash, waterborne colloids, and industrial latexes and pigments have been separated.

Characterization of Powder Surface Areas

In powder studies, the surface area of the powder is an important parameter. It can be measured directly by means of gas adsorption studies, in which the amount of gas or another molecular item, such as dye molecules adsorbed onto the powder to form a monolayer, is determined. Several books have been written describing the theory and procedures for gas adsorption studies. Before 1977, it was believed that one of the basic problems with surface area estimates by gas adsorption was that uncertainties in the knowledge of the cross-sectional area of the adsorbed molecules made the estimates depend on the gas being used (58). In recent years, the gas adsorption studies of surface areas have been reinterpreted from the viewpoint of fractal geometry (59). It is now recognized that the surface area measured, using a given gas, depends on the accessibility of the rough surface to the adsorbed molecules, as illustrated in Fig. 10a. In a study of a series of adsorbent molecules of increasing size, Avnir and coworkers have shown that the surface area estimates can be plotted against the molecular size to obtain a Richardson plot from which the fractal roughness of the powder surface can be deduced (59, 60); a graph generated by Avnir and coworkers is shown in Fig. 10b. The slope of its data line can be used to deduce a fractal dimension of the rough surface. The fractal description of powder roughness is an important parameter for the bioavailability of a drug or the chemical reactivity of powder. Neimark has recently

Fig. 10 Gas adsorption data permit the determination of the fractal dimension of a rough surface. a) The surface is estimated from the number of gas molecules that cover the surface. The estimate depends on the size of the gas molecule; b) the fractal dimension of a surface is derived from the results of gas adsorption studies with several different sized molecules (From Ref. 59.)

described a method for calculating the surface area and roughness of a powder by studying capillary condensation of a liquid on a powder (61).

The fineness of a powder can be studied with the help of permeability techniques, in which the resistance to fluid flow of a powder plug is measured and the fineness of the powder deduced from this measured resistance using various equations such as the Kozeny–Carmen equation. The interpretive equations used to calculate the surface area from permeability measurements make several assumptions concerning the pore structure of the packed powder bed, and the measured surface area from permeability studies should be regarded only as a measure

of fineness and not as an absolute measure of surface. Instruments such as the Fisher Subsieve Sizer and the Blaine Fineness Tester are permeability-based methods that, in the past, have been widely used in industry and are still often used for quality control in industry. A major advantage of permeability methods is that they use large amounts of powder, which minimizes the problems of sampling (62, 63).

PORE-SIZE DISTRIBUTION MEASUREMENTS

When the pore size of a packed powder bed or of the structure of porous powder grains is of interest, mercury-intrusion studies can be used to investigate the pore structure. Fig. 11 shows data of a study using the mercury-intrusion technique to examine the structure of a powder bed of porous grains (64). The amount of mercury entering a bed at different pressures is used to generate the data. Using the known contact angle of mercury with the material of the powder, the applied pressure can be interpreted in terms of the capillary tube through which mercury moves at that pressure. However, there has always been some controversy as to the physical significance of mercury-intrusion data because it only measures access pore diameter, not the volume of the pore behind the neck. (Theories interpreting mercury-intrusion data in terms of pore diameter are often referred to as ink-bottle interpretive models, the idea being that it is the neck of the ink bottle that represents the penetration diameter, not the diameter of the bottle behind the neck.) For the data in Fig. 11a, at low pressures the mercury is entering the voids between the grains of the powder, but when a pressure of approximately 2000 psi (13.8 MPa) is reached, the mercury starts to intrude into pores within the powder grains having access diameters of the order of $0.1\ \mu\text{m}$. It has recently been shown that the traditional way of presenting mercury-intrusion data can be revised to generate a fractal dimension in data space. The revised data in Fig. 11a are shown in Fig. 11c. The slopes α and β of these diagrams are fractal dimensions in data space (65, 66).

STANDARD REFERENCE POWDERS

Some manufacturers of instruments for characterizing fine particles claim that their instruments do not need calibration. Such claims should be treated with skepticism. In practice, many sizing instruments have to be calibrated using standard powders available from several vendors (67, 68). Because the various methods of exploring the size

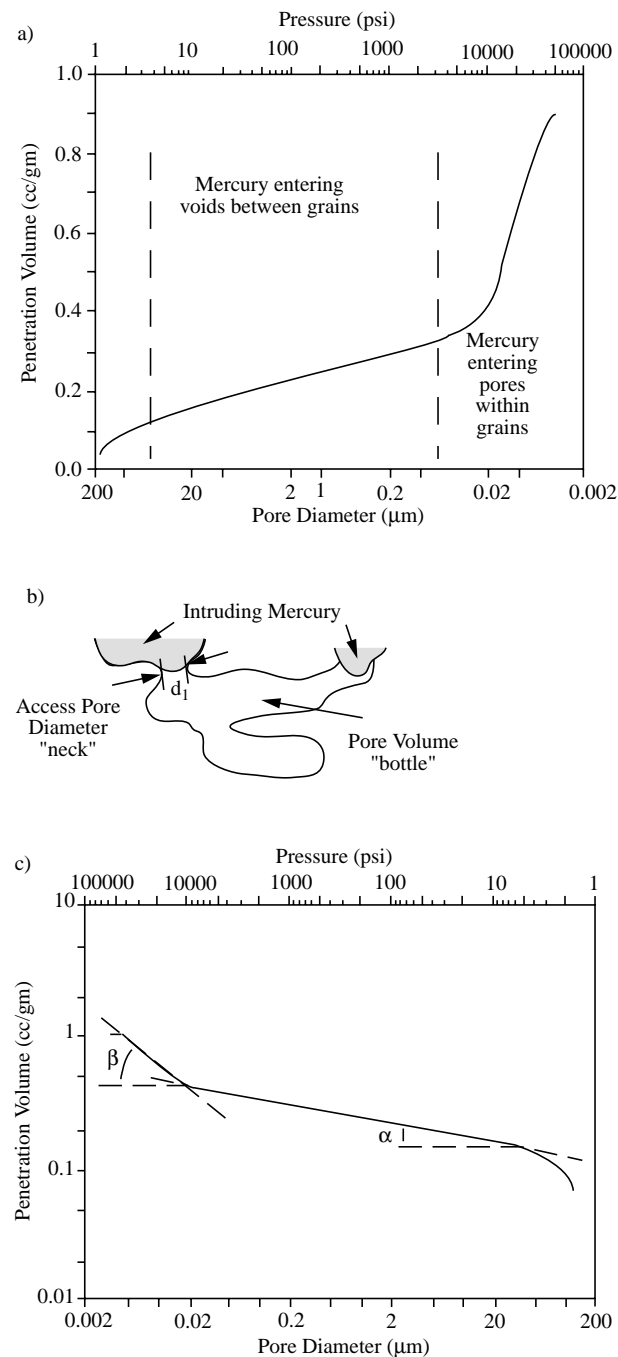

Fig. 11 Mercury intrusion porosimetry involves applying increasing pressure to a sample under study and noting the volume of mercury entering the pores within the sample. a) Traditional representation of mercury intrusion data; b) the physical significance of “ink bottle” theories of mercury intrusion have always been the subject of debate; c) a possible reinterpretation of the data in a) as fractal data. α and β are the slopes of particular regions of the resulting curve, which may be interpreted as fractal dimensions.

distribution of a powder evaluate different physical parameters, the size distributions of a powder generated by different methods do not always agree. The relationship between distribution functions, as evaluated by different methods, should be explored experimentally (69–72).

INTRODUCTION

A thorough understanding of partition coefficients is important to all research scientists and product development staff in various branches of the pharmaceutical field. The principle and applications are involved in several different areas of current pharmaceutical interest. These include the techniques of extraction, preservation of oil–water systems, penetration through packaging materials, absorption and distribution of drugs in vivo, protein binding and hemodialysis, drug metabolism, enzyme inhibition, drug–receptor interactions, drug-delivery systems, and drug targeting. Because the partition coefficient is a measure of hydrophobic-bonding tendency, and all proteins (enzyme, membrane, plasma, and receptor proteins) contain 20 to 45% of amino acids with nonpolar groups (e.g., leucine, isoleucine, phenylalanine, tyrosine, tryptophan, etc.), continuing interest in using partition coefficients in correlating biological activity with molecular structure is expected. Other areas of interest in the application of partition coefficient fall beyond the scope of this article. These include analytical chemistry, toxicology, forensic medicine, ecology, and environmental protection.

HISTORICAL BACKGROUND

The first observation that the ratio of concentrations of a solute (e.g., I_2 or Br_2), when distributed between an organic solvent (e.g., CS_2 or ether) and water, remained constant even when the volume ratio of the immiscible solvents changed widely, was first reported by Berthelot and Jungfleisch in 1872, as illustrated by Eq. 1:

$$P = C_o/C_{aq} = \text{equilibrium constant } K \quad (1)$$

In 1921, Smith suggested that partition coefficient P can be converted from one solvent system to another.

Thirty years later, Collander presented the standard linear free-energy relationship, shown in Eq. 2, using water and different alkanols:

$$\log P_2 = a \log P_1 + b \quad (2)$$

where a is a coefficient, and b is a constant.

At the turn of the century, Meyer and Overton discovered that most organic compounds (except nutrients) penetrate tissue cells as a lipid barrier and that their narcotic action parallels the oil–water partition coefficients of the compounds. In the early 1950s, Collander demonstrated that the penetration rate of plant cell membranes by various organic compounds was related to their oil–water partition coefficients. Cohen and Edsal studied the ratios of alcohol solubility to water solubility to define the relative lipophilic character of amino acids. The limited additivity of the partition coefficients of organic compounds was observed by Collander, Cohen, and Edsal in their studies. In the early 1960s, Salame and Pinsky derived the permachor method, given in Eq. 3, for calculation of the P factor for the prediction of chemicals permeation through a plastic membrane:

$$\log P_f = 16.55 - 3700/T - 0.22\pi \quad (3)$$

where π is the permachor constant, and T is the absolute temperature. A general equation was presented by these investigators, as in Eq. 4:

$$\log P_f = K - R\pi \quad (4)$$

where K is a temperature correction constant, and R is a polymer (e.g., plastic) correction term. Interestingly, at about the same time Hansch, Fujita, and co-workers made the most significant contributions toward the understanding and application of partition coefficients ($\log P$ and π) and greatly extended the linear free-energy-related (LFER) approach from organic chemistry to medicinal chemistry and biology. This renewed interest in the application of partition coefficients has stimulated many excellent reviews, books, and monographs.

THEORY AND EXPERIMENTAL METHODS OF MEASUREMENTS

Because the partition coefficient is measured when an equilibrium is reached, it is characterized by the equality of the chemical potentials μ_o and μ_{aq} of the solute in the two phases (organic and aqueous), as shown by Eqs. 5, 6, and 7:

$$\mu_o = \mu_o^0 + RT \ln C_o \quad (5)$$

$$\mu_{aq} = \mu_{aq}^0 + RT \ln C_{aq} \quad (6)$$

$$\text{If } \mu_o = \mu_{aq},$$

then:

$$\begin{aligned} P = C_o / C_{aq} &= e^{-(\mu_{aq}^0 - \mu_o^0) / RT} \\ &= e^{-\Delta\mu^0 / RT} \end{aligned} \quad (7)$$

where C_o and C_{aq} are the equilibrium concentrations of the solute in the organic and the aqueous phases, respectively; μ_o^0 and μ_{aq}^0 are the chemical potentials (in the organic and aqueous phases, respectively) at infinite dilution; and R is the gas constant, T the temperature, and P the partition coefficient. P is a constant for any compound in a given solvent system at a given temperature; this relationship is known as the Nernst law.

As with any equilibrium constant K , P is related linearly to the standard free-energy change when it is converted to the logarithmic scale, as in Eqs. 8, 9, and 10:

$$\Delta G^0 = -RT \ln K \quad (8)$$

For any equilibrium:

$$\Delta G^0 = -2.303 RT \log K \quad (9)$$

For partition processes:

$$\Delta G^0 = -2.303 RT \log P \quad (10)$$

Because of this linear free-energy relationship (LFER), $\log P$ is commonly used in most correlation studies instead of P .

In the past 35 years or so, 1-octanol-water has been the most commonly used solvent system. It has been shown that for correlation with biological activity, organic solvents (such as 1-octanol) capable of forming hydrogen bonds usually give better correlation than those not capable (e.g., CCl_4 , cyclohexane, and other hydrocarbons). Extensive compilations on 1-octanol-water partition coefficient are available.

On the other hand, if one is interested in separating out thermodynamic properties such as enthalpy change (ΔH) and entropy change (ΔS), a solvent with minimum mutual

solubility with water (such as cyclohexane or heptane) is preferable.

Apparent Versus True Partition Coefficient ($\log P'$ Versus $\log P$)

If a solute is ionizable (either acidic or basic), two different species can exist in the aqueous phase, and therefore the apparent partition coefficient (P') or the true partition coefficients (P) can be measured, as shown below and in Eqs. 11, 12, 13, 14, 15:

where

$$P = [\text{HA}]_o / [\text{HA}]_{aq} \quad (11)$$

$$P' = [\text{HA}]_o / ([\text{HA}]_{aq} + [\text{A}^-]_{aq}) \quad (12)$$

and

$$P = P' / (1 - \alpha) \quad (13)$$

where α is the degree of ionization: for acids:

$$\alpha = 1 / [1 + \text{antilog}(\text{pK}_a - \text{pH})] \quad (14)$$

for bases:

$$\alpha = 1 / [1 + \text{antilog}(\text{pH} - \text{pK}_a)] \quad (15)$$

Because the degree of ionization is a function of the pH of the aqueous phase and the pK_a of the solute, the apparent partition coefficient P' fluctuates as the pH of the aqueous phase (usually a buffer solution) is changed, whereas the true (or corrected) partition coefficient (P) should remain constant. However, in reality the different buffer species may not only affect P' but also P because of different degrees of ion-pair formation and the different polar nature of the counterions used. Among the different buffer species, 1-octanol-phosphate buffer appears to give the most consistent results compared with 1-octanol-water. In some publications, the apparent partition coefficient P' is also described as the distribution coefficient D .

Because the separation of immiscible phases takes place only in the presence of gravity, it would not be possible to measure partition coefficients in outer space where the gravity is zero.

Shake-Flask Method

The shake-flask method is used most commonly in the measurement of partition coefficients. It is also the

standard procedure to validate other methods. A solute is simply shaken with two immiscible solvents (organic and aqueous), followed by analyzing the solute concentration in one or both phases. To avoid any volume changes in both phases, one phase is saturated with the other before the partitioning process. It is important to ensure that equilibrium is reached before the analysis. If a solute does not cause emulsification, vigorous shaking can reduce the time required to reach equilibrium, usually in a few minutes. However, if a solute with both polar and nonpolar groups present (such as saponin glycosides or surfactant-type compounds), a gentle and slow shaking procedure or even special devices such as a Doluisio and Swintosky Y-tube or a Schulman-type cell should be used.

Some true (undissociated, corrected) partition coefficients of representative drug molecules ranging from -2.26 to $+15.69$ are shown in Table 1.

For the quantitative analysis of the solute distributed in one or both phases, the most commonly used analytical methods include UV-visible spectrophotometric analysis for compounds with chromophore groups and gas-liquid chromatography (GLC). Colorimetric methods have also been used for specific compounds.

With the proper choice of solvent volume and sensitive analytical methods, $\log P$ values ranging from -5 to $+5$ can be measured. The temperature dependence of many partitioning systems is on the order of 0.01 log unit per degree in the 25°C range. Adequate temperature control is needed for high accuracy. This is more critical for volatile solvents like ether, chloroform, low-boiling hydrocarbons, and alcohols lower than 1-octanol.

Chromatographic Methods

In recent years, the availability of reproducible systems and precision instruments in high-performance liquid chromatography (HPLC) has prompted the application of chromatography in the rapid measurement of partition coefficients. In general, a linear relationship between $\log P$ and $\log K'$ from a set of compounds is required for the interpolation or extrapolation of $\log P$ values of additional compounds of congeneric nature, as shown in Eq. 16:

$$\log P = a \log K' + b \quad (16)$$

where the capacity factor K' is determined from the net retention time t_R relative to the nonadsorbed time t_0 , as defined by Eq. 17:

$$K' = (t_R - t_0)/t_0 \quad (17)$$

This is similar to the linear relationship R_m measured by thin-layer chromatography (TLC), given in Eq. 18:

Table 1 Selected true (corrected) partition coefficients of representative drug molecules measured in 1-octanol-water or 1-octanol-phosphate buffer

Drug	log P

Propoxyphene	4.18
Mefepristone (Ru486)	5.48 ^b
α-Tocopherol (vitamin E)	12.28 ^a
β-Carotene	15.69 ^a

^aCalculated value using CQSAR program of BioByte.

^bCalculated from the $\log P$ of progesterone and the π values of the substituents: $\log P_{\text{Ru 486}} = \log P_{\text{progesterone}} - \pi_{\text{CH}_3} + \pi_{\text{double bond}} + \pi_{(\text{CH}_3)_2\text{N}^+} - \pi_{\text{COCH}_3} + \pi_{\text{O}=\text{C}} + \pi_{\text{CH}_3} + \pi_{\text{OH}} = 3.87 - 0.5 - 0.2 + (-0.18) + 1.96 - (-0.71) + 0.48 + 0.5 + (-1.16) = 5.48$.

$$R_m = \log K' = \log[(1 - R_f)/R_f] = \log(1/R_f - 1) \quad (18)$$

Because of the limits inherent in the mathematical formula, R_m ranges only from -1.996 to $+1.996$ for all possible compounds. This makes it less sensitive than the direct measurement of $\log P$. Nevertheless, for many compounds, it is much easier and more economical to measure $\log K'$ or R_m than $\log P$.

Countercurrent and Filter Probe Methods

A countercurrent-based device, known as AKUFVE, is useful when a large amount of information resulting from varying T or pH is required on one or only a few compounds. This method has the disadvantages of difficulties in cleaning and operation as well as in the need of large quantities of materials. Another method is Tomlinson's filter-probe method, which samples the phase with the larger volume (generally the aqueous phase) and pumps it through a UV detector to monitor the state of equilibrium. A heavy metal probe is attached to the circulating stainless steel tubing with a special filter that prevents entrapment of the unwanted phase. This method is related to the shake-flask method at high phase-volume ratio. It may be useful for unstable compounds and, as a closed system, may be used over a wide temperature range. Kaufman et al. have reported a microelectrometric titration method for the direct measurement of the pKa and partition and distribution coefficients of narcotics and narcotic antagonists and their pH and temperature dependence. Based on this principle, an automated instrument is now available for the simultaneous measurement of pKa and $\log P$ (pION Inc., Cambridge, MA).

Calculation of Partition Coefficients

Hansch-Fujita π constant

In 1964, Fujita et al. proposed that $\log P$ was an additive-constitutive property and can be calculated by taking the sum of the $\log P$ of the parent molecule and the π of the substituent, as in Eqs. 19, 20, 21:

$$\log P = \Sigma \pi \quad (19)$$

$$\pi_{\text{substituent}} = \log P_{\text{substituted molecule}} - \log P_{\text{parent molecule}} \quad (20)$$

For example:

$$\begin{aligned} \pi_{\text{CH}_3} &= \log P_{\text{CH}_3\text{C}_6\text{H}_5} - \log P_{\text{C}_6\text{H}_6} = 2.69 - 2.13 \\ &= 0.56 \end{aligned} \quad (21)$$

$$\log P_{\text{Cl}(\text{C}_6\text{H}_5)\text{CH}_3} = \log P_{\text{C}_6\text{H}_6} + \pi_{\text{Cl}} + \pi_{\text{CH}_3} = 2.13 + 0.71 + 0.56 = 3.40 \text{ (calculated), measured value} = 3.33.$$

By definition, the π of hydrogen is zero. A scale of the π values of various groups from very hydrophilic to very hydrophobic is shown in Table 2. Extensive compilations of the π constants of various functional groups are available in the literature.

Rekker's fragmental constant f

The fragmental (reductionist) approach of calculating $\log P$ was initiated by Rekker and coworkers. Based on a collection of measured $\log P$ values, they applied statistical analysis to determine the average contribution of simple fragments such as C, CH, CH₂, CH₃, OH, NH₂, CONH₂, OCH₃COOH, etc (see Table 2). It was found that it was necessary to introduce corrections if two polar groups were separated by only one or two aliphatic carbons. Their postulation is given in Eq. 22:

$$\log P = \Sigma a_m f_m + \Sigma b_m F_m \quad (22)$$

where a = the number of occurrences of fragment f of type n , and b = the number of occurrences of correction factor F of type m .

Leo-Hansch f constant

Hansch and Leo used a constructionist (synthetic) approach by starting with a few carefully measured values of $\log P$ of simple structures like H₂ and CH₄ and derived a separate set of fragment constants. The two columns in Table 2 show the slightly different values obtained by the two groups. Different π and f values should be used for an aliphatic system.

It is worth noting that although π_{H} is zero, f_{H} according to the Rekker's scale is 0.18 and according to the Hansch–Leo scale is 0.23. The calculation of $\log P$ using the fragment method has been computerized by the Hansch–Leo group. In this CLOGP program, all known correction factors have been incorporated. The structure of any compound can be entered by a linear notation called SMILES, and by going through a substructure search algorithm GENIE, the $\log P$ value can be calculated according to Eq. 22. The SMILES program includes all isomerisms.

Other methods

Other published methods of estimating partition coefficients include the use of molecular surface and volume in predicting solubilities and free energies of desolvation and the application of principal-component analysis based on partition coefficient data. Suzuki and Kudo's CHEMICAL (Combined Handling of Estimation Methods Intended for Completed Automated $\log P$ Calculation) as well as a

multidescriptor highly nonlinear regression model proposed by Bodor et al. were applied, in which a 10-parameter (15-term) equation was used to correlate with the log P values of 118 compounds of varying complexity. (All the descriptors were derived from AM1 calculation and were related to the surface area, dipole moment value, and charge densities of the molecule.) Some of the terms were raised to 10^4 and 10^2 powers to give the best fit. It is difficult to explain the physical meaning of the highly complex polynomial equation.

Several experts in the field suggest that the ultimate goal of flawless calculation of log P has not yet been fully realized, especially when dealing with a highly complex structure with de novo functional groups.

Physical Factors Contributing to Log P or π : Bulk and van der Waals Forces, Dipolar Interactions, and Hydrogen Bonding

Over the past 25 years, considerable efforts have been devoted to delineate the fundamental nature of partition coefficients (log P or π). As a result, many correlations between log P (or π) with other structural descriptors or physicochemical parameters have been reported by various investigators. For example, Moriguchi et al. dissected log P into two intrinsic components, namely, molecular volume and polar effect, and showed that the partition coefficient of a nonpolar molecule is a linear function of the volume. For polar molecules, a hydrophilic group effect has to be added as a correction term in the evaluation of log P . Kamlet et al. correlated log P with the solvatochromic parameters π^* and β , which were derived to measure dipolar and hydrogen bond acceptor strengths of pure bulk solvents as well as the corresponding properties of solutes.

Franke et al. examined the dependence of hydrophobicity on solvent and structure and showed that log P values depend on solute bulk and polar and hydrogen-bonding effects. Ou et al. examined the quantitative relationship of log P with molecular weight (log MW), dipole moment (μ), and hydrogen-bond capability (HB_2) of various compounds. For 222 of 282 compounds, log P values were correlated with these three parameters with a correlation coefficient of 0.938 and standard deviation of 0.492, as shown in Eq. (23):

$$\log P = 5.84 \log MW - 0.36 \mu - 0.77 HB_2 - 8.86 \quad (23)$$

$n = 222$, $r = 0.938$, $s = 0.492$ where HB_2 is the sum total of energy decrement in a hydrogen-bond group.

In a similar manner, Yang et al. reported the general Eq. (24) to be applicable to a wide range of nonpolar and polar substituents (with only a few notable exceptions):

$$\pi = +a MW (\text{or } \nu W) - b HB - c \mu + d \quad (24)$$

where νW is the van der Waals volume, and HB can be the number of atoms in a group capable of forming H bonds (HB_1), or $HB_1 \times$ energy (HB_2).

This general model has been extended to the log P of disubstituted aromatic compounds and the solubilities of tetracycline derivatives.

Applications

Extraction

In both organic and analytical chemistry laboratories, it is a common procedure to extract a compound from one solvent to another. It is also a common knowledge that it is more efficient to use small volumes and multiple

extractions. This is shown by Eqs. 1 (given previously) and 25, 26, 27, assuming the two solvents are completely immiscible (e.g., $\text{H}_2\text{O}-\text{CCl}_4$).

$$P = (W_o/V_o)/[(W - W_o)V_{aq}] \quad (25)$$

or

$$\text{or } W_o = WPV_o/(PV_o + V_{aq}) \quad (26)$$

after n extractions:

$$W_n = W[PV_o/(PV_o + V_{aq})]^n \quad (27)$$

where W is the water phase, and V is the volume.

If two solvents are partially miscible (e.g., ether- H_2O), the equation provides only approximate values, which may still be useful for practical purposes.

Preservation of oil–water systems

Many pharmaceutical preparations containing oil–water systems (creams, ointments, or suspensions) are subject to microbial contamination. Bacteria in these heterogeneous systems are usually grown in the aqueous phase and at the oil–water interface. To preserve the shelf-life of these preparations, benzoic acid or other organic acids are added as preservatives. Because the microbial cell membrane is lipophilic in nature, the bacteriostatic actions of the acidic preservative are attributable almost entirely to the undissociated acid and not to the ionized form. A good understanding of the partition coefficient and the degree of ionization allows accurate calculation of the free un-ionized acid in the aqueous phase, which provides the bacteriostatic concentration.

Quantitative structure-activity relationships (QSAR)

Since the early work of Hansch et al., numerous examples of the quantitative correlation of biological activity with chemical structure have been reported. The success of QSAR relies heavily on the use of partition coefficients ($\log P$ or π) in extending the linear free-energy relationship (LFER) from homogenous organic chemical systems (i.e., the Hammett–Taft type approach) to compartmentalized heterogeneous biological systems.

Further analysis of the physical nature of the partition coefficient reveals that it is a composite property depending on size, shape, dipole moment, and hydrogen-bonding ability. Although many researchers have attempted to replace $\log P$ with other simple parameters, only limited success has been achieved for some, but not all, molecules. It appears that for entirely new complex molecules, it still would be necessary to measure the partition coefficient, preferably validated by the conventional shake-flask method.

Partition coefficients of peptides and ampholytes

Since the publication of the first edition of the *Encyclopedia of Pharmaceutical Technology*, significant progress has been made in the experimental measurements and calculation of the $\log P'$ values of small peptides ranging from di- to pentapeptides with and without ionizable side chains. Additional work will be needed to calculate the $\log P'$ values of large peptides and proteins. Testa's group has used a potential-pH representation to show ionic partition diagrams and analyzed the lipophilicity profiles of amphoteric compounds. They have also compiled a review on various computational approaches to lipophilicity, with 223 references cited.

Because an increasing number of new compounds are being synthesized every day, it is not feasible to have the partition coefficient of every new structure experimentally determined. According to the estimate of Leo and Hansch, the measured $\log P$ in octanol/water increases at the rate of approximately 1200/year. When a close congener with measured $\log P$ is available, it is easier to use the $\Sigma\pi$ method in calculating the $\log P$ of a structurally similar new derivative. On the other hand, for a large number of different structures, the CLOGP method based on the f constant of Hansch and Leo is suitable for obtaining calculated $\log P$ values fairly efficiently. An impressive correlation ($r^2 = 0.98$, $s = 0.21$) between the measured $\log P$ and calculated $\log P$ values of 9000 compounds has been obtained by this group. Regardless of the method used, it is necessary to measure the $\log P$ of a few model compounds for comparison. Many times, careful examination of the large deviation between the experimentally measured and the theoretically calculated values can uncover intra- or intermolecular interactions and thus lead to a better understanding of the phenomenon of partitioning of a solute between two immiscible phases saturated with each other.

The initial development of the fragmental constant f by Rekker has stimulated that of the systematic CLOGP method. Rekker has further compared the model of partition process with the passage of a ball through a “brick wall” to account for a frequently observed “magic number.” The model does not take into account the fact that neither 1-octanol nor the aqueous phase consists of homogeneous and ordered “bricks” as depicted in his diagram. At the present time, there is no rigorous theoretical method available for the calculation of $\log P$ of a complex de novo structure. Therefore, semiempirical methods and experimental methods will continue to be used.

For QSAR analysis, distribution coefficients (D) of ionizable compounds have been used by some investigators. From the mathematical formula of D , it can be

demonstrated that it is the same as the apparent partition coefficient (P') and can be easily converted to a true (or corrected) partition coefficient P , as shown in Eqs. 28, 29, 30:

$$D = [HA]_o / ([HA]_{aq} + [A^-]_{aq}) \quad (28)$$

$$P' = [HA]_o / ([HA]_{aq} + [A^-]_{aq}) \quad (29)$$

$$D / (1 - \alpha) = [HA]_o / [HA]_{aq} = P \quad (30)$$

If limited data points are available in QSAR analysis, $\log P'$ ($\log D$) can be used to account for different degrees of ionization as well as for different lipophilicities. If, on the other hand, a sufficient number of data points are available (more than 5 data points for each parameter being examined), it will be advantageous to use the log of the [undissociated] vs. [dissociated] ratio $\log U/D$ ($= pK_a - pH$ for acids, and $pH - pK_a$ for bases) as an independent variable as well as $\log P$. This will separate the effect of ionization from that of relative lipophilicity.

Avdeef has recently reported the refinement of partition coefficients and ionization constants of multiprotic substances based on a generalized, weighted, nonlinear least-squares procedure and pH titration curve. This method allows for the determination of pK_a and $\log P$ values of multiprotic substances with fairly close ionization constants.

A Prolog P program has been developed for the estimation of the distribution coefficients ($\log D$) of ionizable compounds, based on LFER-derived microscopic dissociation constants. Several estimation methods for calculating octanol-water partition coefficients have been reported (e.g., $\log KOW$; $X \log P$) using atom/fragment additive principles and correction factors. Clarke et al. have reported that for ionizable compounds, by using two different octanol volumes in a dual-phase potentiometric titration, both pK_a and partition coefficient values can be obtained by curve fitting.

PATENTS—INTERNATIONAL PERSPECTIVE

Stuart R. Suter

Suter Associates, Glenside, Pennsylvania, U.S.A.

Peter J. Giddings

SmithKline Beecham plc, Brentford, United Kingdom

INTRODUCTION

A strong patent system is important to the research-based pharmaceutical industry. The success of the pharmaceutical industry has been based on the discovery of new products that treat human disease states in new and unique ways. The patent system has provided protection for these innovative products for a period of time, allowing the industry to use the revenues gained to search for the next generation of products that will improve the health of society. It is important that persons in R&D of the industry understand the basic principles of the patent system.

WHAT IS A PATENT?

A patent is a grant of exclusive rights from a government to inventors for their invention in exchange for the inventors disclosing their inventions to society. This quid pro quo is valuable to society because the disclosure stimulates additional innovation and development. The alternative for inventors is to keep their inventions secret and thus deprive society of the opportunity for further advancement.

Patent rights are limited in time and are also limited to the sole right of excluding others from making, using, and selling the invention. Because governments grant these rights, they are effective only in the area controlled by that government. Thus, a United States patent provides protection only in the United States and its territories such as Puerto Rico. If inventors desire protection in Japan, Canada, or any European country, they must apply for a patent in each of those countries as well.

It is important to understand that this right granted by the patent is solely a right to exclude others. It does not carry with it the right to practice the invention by the inventors themselves. This right to use by the inventor may be limited by the existence of other patents that would be needed to practice the invention or by laws or regulations having nothing to do with patents. An example of the latter

is the health registration regulations in the countries where pharmaceutical products are being sold. An inventor not being free to use his invention because of other patents is also a common situation. For example, party X may have a patent claiming a broad genus of compounds useful to treat hypertension. Our inventor discovers a specific compound not disclosed specifically in the patent of party X, but through selection of the appropriate substituents in the defined genus this compound can be found. Its hypertensive properties are far superior to those of the compounds specifically disclosed in party X's patent, thus this inventor can obtain a patent for the compound but must obtain permission from party X before marketing the compound because of the patent rights of party X.

Patents belong to class of property that is referred to as "intellectual property." Intellectual property also includes trade secrets, trademarks, registered designs, and copyrights.

A trade secret is any information unknown to the public but gives the owner an economic or competitive advantage. Trade secrets have value only as long as they remain secret, which is difficult in this modern age. In the pharmaceutical industry, it is rare for any invention to be maintained as a trade secret because in the interests of public safety, the chemical composition of pharmaceutical products is always made public.

A trademark is a word, name, or symbol that identifies the source of the goods to which it applies. Two or more companies can sell the same product, but the public can identify each company's goods by the trademark. Pharmaceutical products available from multisources carry the same generic name and also the unique trademark of the specific seller; an example is the Tagamet brand of cimetidine.

A copyright protects the creations of artists and authors. In the pharmaceutical industry, copyrights are used to protect advertisements, product literature, and other copy used for product promotion.

A registered design right protects the aesthetic appearance of an article, i.e., features of a product's appearance rather than its technical features. In the

pharmaceutical industry, a registered design right might be obtained, for example, in respect to a particular tablet shape or to the appearance of the product's packaging.

The patent system traces its history to early Venice, where patents were granted at least as early as 1460. The Anglo-American systems have their origins in Great Britain, where Parliament enacted the Statute of Monopolies in 1624. This law provided the basis for the British patent system for many years. The American colonies, before achieving independence, had no power to grant patents for inventions under the British system. The basic U.S. patent system is founded on the U.S. Constitution. Article I, Section 8, gives Congress the power "to promote the progress of science and useful arts by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries." The first Patent and Copyright Act in the United States was enacted on April 10, 1790.

PATENTS AND PHARMACEUTICALS

The patent system as applied to pharmaceuticals has been one of great controversy over the years. Many countries, especially those with few technology-based industries, have held that providing protection for drug products is against society's interests. Some countries include food in this category as well. Based on this theory, patents for pharmaceutical products have been limited or not allowed at all. The premise is usually that patents for chemical compounds can be claimed only for the process by which they are prepared. Thus, if someone develops a different process to make the compound, he or she can avoid the patent of the innovator.

Historically, as a country becomes more industrialized, it strengthens its patent system by providing protection for compounds per se, often referred to as "product protection." Examples are Germany and Japan, which had process protection for pharmaceutical products until 1968 and 1978, respectively, when they amended their laws to provide product protection. China had no patent law until June 1, 1985, when it introduced process-only protection for pharmaceuticals. Effective January 1, 1993, China amended its patent laws to allow product protection.

Since 1986, discussions have been ongoing at the governmental level to try to improve the standard of intellectual property laws around the world. These discussions, which have primarily been part of the General Agreement on Tariffs and Trade (GATT) negotiations among countries, culminated in 1994 with the signing of an agreement on Trade Related Aspects of Intellectual

Property Rights (TRIPS). This agreement established comprehensive standards for the protection and enforcement of intellectual property rights and became effective in January 1995. The agreement is complex and covers a wide range of patent-related issues including, for example, the provision of patent protection for compounds per se and the provision of a patent term of 20 years from filing. As a general rule, the date of application of the agreement for countries classified as "developed" was January 1, 1996, and for "developing" countries January 1, 2000. The "least-developed" countries have the option to defer application of the agreement until January 1, 2006.

In summary, patent protection for pharmaceutical products has improved significantly in recent years and will continue to improve.

New compounds are not the only inventions important to the pharmaceutical industry. Many products have been developed from sources in nature, such as extracts from plants or compounds isolated from fermentation broths from various microorganisms. Protecting these inventions has been difficult at times in various countries because the materials were present in nature and thus were viewed as natural products, not new or novel. These difficulties can be overcome in certain cases by claiming the compounds in their pure form.

Patenting of "living matter" changed dramatically with the arrival of biotechnology methods and procedures. In 1980, the U.S. Supreme Court decided the famous *Diamond vs. Chakrabarty* case. In this case, a new strain of bacteria, produced by a reproducible artificial procedure, had the ability to digest oil and thus was useful in dispersing oil slicks. It was important to have patent protection on the bacteria per se because they were used themselves and not in a process to produce another product. Certain groups and individuals in the public sector expressed great concern that this decision would lead to patenting other higher forms of life. In 1988, U.S. Patent No. 4,736,866 was issued, claiming the "Harvard Mouse." This transgenic mouse has the special property of having an oncogene sequence in the germ and somatic cells that makes the mouse useful in testing for carcinogenic materials or for compounds that confer protection against neoplasms. Since then, many patents for higher life forms (but not humans) have been issued.

In Europe, the issues surrounding the patentability of biotechnological inventions are the subject of vigorous ongoing legal and political debate. In July 1998, the European Parliament approved Directive 98/44/EC aimed at harmonizing laws across Europe with respect to the patenting of biotechnological inventions. Member states had until July 2000 to bring their laws into conformity

with the directive. However, the Dutch government has issued a challenge to the legality of the Directive at the European Court of Justice, and the decision of the court is awaited.

With respect to the specific case of the Harvard Mouse, an equivalent European patent has been allowed, but it is currently under opposition by a number of parties at the European Patent Office (EPO). Thus, the status of the patent is unclear at this time.

INTERNATIONAL TREATIES AND SYSTEMS

As noted above, patent protection is obtained on a country-by-country basis, and therefore patent applications must be filed in each country where protection is desired. International treaties and regional conventions have been set up to coordinate and make obtaining worldwide protection convenient and efficient. Several important treaties have been developed and are administered by the international organization known as the World Intellectual Property Organization (WIPO), centered in Geneva, Switzerland.

Paris Convention

This is the short title for the Paris Convention for the Protection of Industrial Property. This treaty was first signed in Paris in 1883 by 11 countries and has been revised several times over the years. Today 157 countries have ratified this treaty. A notable country of concern to the pharmaceutical industry that is not a member of the Paris Convention is Taiwan.

An important feature of the Paris Convention allows applicants to claim priority to their first-filed application in any member country, provided the applicant files a patent application in that country within 1 year. This is referred to as convention priority, and it is of great importance in the patent strategies developed in the pharmaceutical industry, as described below. If the first application meets the conditions of the Convention, the applications in all member countries are treated as if they were filed on the same day as the first application.

Budapest Treaty

When an invention involves a microorganism, most countries require the deposit of the biological material to complete the disclosure. WIPO established international uniformity under the Budapest Treaty of 1977, which became effective in 1980 and has been ratified by

48 countries. It provides for the establishment of a group of international deposit authorities. When a strain of microorganisms is deposited in any one of these authorities, this single deposit satisfies the necessary requirements for all signatory countries of this treaty. Under this convention, the formal requirements for making the deposit and maintaining the culture are set forth. Included in this is the possibility of a redeposit should the initial deposit become nonviable. The maintenance period of the deposit is a minimum of 30 years from the date of deposit.

Patent Cooperation Treaty (PCT)

The PCT first came into force in January 1978. It is in effect in 109 countries, including the United States, all the countries of the European Patent Convention, Japan, Canada, and China, as of January 1, 2001.

This treaty puts forth a process by which an applicant, through a simplified procedure, can file one application and designate that it be treated as an application in one or up to all of the PCT member countries. This application is filed in one of the official receiving offices in any of the official languages—English, German, French, Chinese, Japanese, Russian, and Spanish. The PCT has become a very important procedure in the pharmaceutical industry in providing an efficient means of obtaining maximum patent protection around the world in the most efficient and cost-effective manner.

The PCT application can be filed under the terms of the Paris Convention at the end of the 1-year period from the priority filing. The receiving office passes the application on to an International Searching Authority through which a search for the novelty of the invention is carried out. The application, together with the search report, is published 18 months from the priority date. After this publication, the applicant can choose two avenues for his application. First, if she or he wishes to proceed directly to each of the designated countries, the filing can be perfected in each of the designated countries within 20 months of the priority date. This is done by submitting the formal documents, translations, and fees required by each local patent office in each designated country. Alternatively, by the end of 19 months, a “demand” can be filed that the Preliminary Examining Authority of the PCT carry out a preliminary examination for patentability. This examination takes place between the 19th and 28th months of the priority date. During this period, the applicant receives the results of the examination and has the opportunity to present arguments in support of the patentability of his invention and/or amend his application. Again, the applicant must submit all formal documents, translations, and fees

required by each designated country to perfect the individual national filings by the end of the 30th month.

The main advantage of the PCT process is that it allows the applicant time to determine more clearly the commercial viability and importance of the invention. In the pharmaceutical industry, patents are filed on new potential products very early in their development. Many of these fall by the wayside during the development process. The PCT allows for an application to be filed and maintained with minimum expense up to the 30th month before the significant expense of national filing fees and translations is required. Thus, under a strategy using the PCT, the pharmaceutical company can maintain patent applications for the major economically important countries at minimum cost while having 30 months in which to study the invention and determine its commercial potential.

This treaty has been gaining in popularity and use in recent years. In 1999, the PCT was used to file 74,023 applications, compared with 14,874 in 1989 and 2,625 in 1979.

European Patent Convention

A regional system is one that arises from a regional treaty entered into by a number of countries within a geographic area. The European Patent Convention (EPC) is the most important of several regional patent systems. It was negotiated by a number of European countries and entered into force on October 7, 1977. Eight countries ratified it by the time the European Patent Office (EPO) began accepting applications on June 1, 1978. As of January 2001, 20 countries have ratified the EPC. In addition, six other countries, including Slovenia and Romania, have indicated that granted European patents can be validated to have effect in their countries as an alternative to applying for national applications in those countries.

Under the EPC, applicants can file one application in the EPO and designate in which of the 20 countries they desire the application to have effect. The application is examined by the EPO, and if the invention is found patentable, the application is granted, not as a single patent, but as a national patent for each country designated by the applicant at the time of filing. Under the EPC, it is possible to challenge the grant of the patent, provided the challenge is made within 9 months of the patent grant. This provides the opportunity potentially to have the patent declared invalid in one set of proceedings. This procedure is referred to as an opposition and still takes place in the EPO. If there is no opposition filed to the grant of the patent, then challenges to validity of the patent and enforcement need to take place in each country under the national patent laws of that country.

This convention provides an efficient means of obtaining patent protection in up to 26 countries through the filing and prosecution of only one application. When the EPC first went into effect, there was concern that if the prosecution was unfavorable, the applicant would not have any patent protection, whereas if the national system had been used, he would. With the passage of time, this concern has been greatly diminished, and now the convention is used by most, if not all, in the pharmaceutical industry on a routine basis.

Other Regional Systems

There are a number of other regional patent application systems in operation. In Africa, two regional systems operate: the African Regional Industrial Property Organization (ARIPO), formed in 1976, and the African Intellectual Property Organization (OAPI), formed in 1962. These systems have 11 and 15 member states, respectively. In the Middle East, the Gulf Co-operation Treaty operate to provide protection in six countries (for example, Saudi Arabia and The United Arab Emirates), and the Eurasian Patent System operates to provide protection in nine countries of the former Soviet Union, including Russia.

CLAIMABLE INVENTIONS IN THE PHARMACEUTICAL AREA

Section 101 of the U.S. Patent Law defines inventions and discoveries for which a patent can be obtained in very broad terms. Specifically, these are processes, machines, articles of manufacture, and compositions of matter, or any new and useful improvements of these. Article 52 of the EPC provides that a patent will be granted for any inventions that meet the three requirements for patentability. It then lists exclusions, which include “scientific theories and mathematic methods” in addition to medical treatments, as noted below. Many different inventions arising from research in the pharmaceutical field can be protected under these broad definitions.

Chemical Inventions

In the pharmaceutical field, chemical inventions have become of primary importance. The traditional inventions for which the pharmaceutical industry has sought patents are set forth in Table 1.

Specifically, a new composition of matter (NCM) or new chemical compound prepared by synthetic methods is the primary area of interest. They may be made using

Table 1 Potential chemical inventions

Compound per se
Pharmaceutical compositions of new compounds
New pharmaceutical compositions of existing compounds
Method of treatment, mechanistically or by disease state or both
Compound for use (broad first use)
New medical use for existing compound (second use)
Analogy processes for new compounds
Process per se (when novel and inventive)
Intermediates
Processes for preparing compositions
Different salt forms, hydrates, or polymorphs

synthetic methods or are isolated from natural sources such as plant or oceanic material or from fermentation broths. At times, a compound is known in an impure state that is unusable as a pharmaceutical product. If it is obtained in a purified state and meets the requirements of patentability, it can be claimed as a compound of a defined purity.

In addition to the compound per se, chemical processes for the preparation of the compound can be claimed. Analogous processes, which are a known chemical reactions that produce a new compound or use new starting materials, have various standards of patentability in different countries.

Pharmaceutical compositions of the new compound or new improved formulations of existing compounds are also patentable. For a new drug-delivery system, patent protection can be very important and useful, especially if developed for the delivery of an existing product.

A method of treating a particular disease or physiological condition is another important type of invention in the pharmaceutical field. It may be necessary to claim this type of invention by what is called “Swiss claims” to overcome the industrial applicability requirement in Europe. Such claims take the form of claiming the compound for use in the manufacture of a medicament for the treatment of a particular disease state. In the United States, the applicant may be required to provide proof to support the treatment claim. This is especially true if the invention is treating a disease that has been difficult or impossible to treat in the past, e.g., cancer or AIDS. A claim to “a method of treating cancer with compound X” will be challenged during examination. The most likely result will be amendment of the claim to a method of treating the specific cancer for which data can be provided to demonstrate utility.

Biotechnology Inventions

With the blossoming of biotechnology in the 1980s and, more recently, of genomics, a whole new specialty in

Table 2 Potential biotechnology inventions

Recombinant/genomics
The protein per se
Antibodies that react specifically with the protein and antiidiotypic antibodies
rDNA that encodes the protein
Expression systems
Recombinant host cells containing the DNA
Processes to make protein using recombinant host cells
Processes for purifying the protein
Processes to produce the antibody and antiidiotypic antibodies
Methods of using the DNA sequence
Pharmaceutical compositions of the protein
Method of treatment
Vectors
Promoters
Single nucleotide polymorphisms (SNPs)
Expressed sequence tags (ESTs)
Genomic DNA
Monoclonal antibodies
Monoclonal antibody (Mab)
Hybridoma that produces Mab
Process to prepare Mab
Method to use Mab
Pharmaceutical composition of the Mab
Novel antigen and related processes and methods

patent law has developed. In general, it is viewed that the principles of chemical patent practice apply equally to the biotechnology field. The Court of Appeals for the Federal Circuit (which is the U.S. Federal Court that hears all patent appeals from the Patent and Trademark Office and any Federal District Courts) has affirmed this in their decisions. Biotechnology inventions must satisfy the standard statutory requirements in the same manner as for any other invention. From the list of claimable inventions in Table 2, it is clear that biotechnology techniques have resulted in the production of inventions previously not obtainable by classic chemical methods.

REQUIREMENTS FOR PATENTABILITY

There are three basic requirements for patentability: novelty; nonobviousness or inventive step; and usefulness or industrial applicability. Each requirement may differ from country to country and is set forth by the statutes and regulations of each country.

Novelty

The first principle of patent law is that to obtain a patent, the invention must be new. The statutory requirements for novelty are set forth in Section 102 of the U.S. Patent Law and in Article 54 of the EPC.

In the United States, Section 102 has several stated requirements. One is that the invention must not have been known or used by others in the United States or patented or described in a printed publication in the United States or in any foreign country before the invention was made by the applicant. The second provision is that the invention must not have been patented or described in any printed publication anywhere in the world more than 1 year before the date of application in the United States. This is the 1-year grace period available in the United States but not in the rest of the world. These requirements are grouped under the term “anticipation” and mean that a single prior art reference must show the invention being claimed to nullify novelty. If an essential part of the invention is not present in a single publication, but is found in a second reference, anticipation does not exist (however, see the next section on obviousness).

Article 54 of the EPC defines an invention as “new if it does not form part of the state of the art.” It goes on to specify that the state of the art comprises “... everything made available to the public by means of a written or oral description, by use or in any other way before the date of filing....”

Nonobvious or Inventive Step

In many cases, the requirement of nonobviousness or inventive step as it is referred to in Europe, is the one that presents the most difficulty during the examination process. It is governed by Section 103 of the U.S. Patent Law and by Article 56 of the EPC. The general principle is that even though an invention is novel, a patent cannot be granted unless the inventor has done something more than one would expect any given person to have done in the art or field to which the invention pertains. Two or more references can be used to make the case of what would have been obvious to the given person skilled in the art. In the pharmaceutical field, chemical compounds are often known that are very close structurally and/or have similar utilities to the compounds claimed in the application. In these situations, the issue of proving nonobvious is the of most concern during the examination process.

Usefulness or Industrial Applicability

This requirement is covered by Section 101 of the U.S. Patent Law and by Article 57 of the EPC.

In the United States, usefulness is a very broad concept and does not mean a commercial utility is in hand. In the pharmaceutical field, a showing of in vitro test results that have some nexus with treating a physiological condition is sufficient to meet this requirement. If, however, the invention is useful only as a scientific curiosity, this requirement is not met. Chemical intermediates may or may not have the required usefulness. If they are useful to prepare products that are themselves useful then they are patentable. However, intermediates that are only useful to prepare compounds with no utility are not patentable.

In Europe, industrial applicability is required. This means, for example, that methods of medical treatment or diagnosis performed on a human or an animal are not susceptible to industrial application. Nevertheless, substances that are useful in these methods are patentable.

OBTAINING A PATENT

When an invention is made, consideration must be given as to whether to obtain patent protection. Companies have a variety of internal procedures to determine when and where to seek patent protection.

After it has been decided to obtain patent protection, a patent application is prepared and filed. This first filing is referred to as a priority filing and the filing date as the priority date. This is the date against which the invention will be judged for purposes of determining whether a patent should be granted, as discussed above.

Filing Applications

This first patent application is usually filed in the home country of the inventors. In many countries, there are laws and/or regulations that require this, or, if the inventor wants to file in another country first, certain requirements must be met. In the United States, there are regulations against exporting technology to other countries without government approval. An invention made in the United States must be filed first in the United States and not in any foreign country for 6 months after this filing without obtaining an export license from the U.S. Patent Office. If the applicant wishes to file first in another country, he or she must submit the application to the U.S. Patent Office and obtain the export license before filing in that country.

After the priority application is filed, the applicant must decide in what additional countries the application should be filed during the 12-month convention period available under the Paris Convention. This is often referred to as the foreign filing decision. The cost of protecting the invention

is directly proportional to the number of applications filed and the different language translations required by these filings. In times of cost consciousness, this foreign filing decision is not taken lightly.

Several options are available to applicants at this time. The first is to obtain a patent only in their home country and not pursue patent protection elsewhere. The second possibility is to proceed with a foreign filing in one or more foreign countries within the convention year. A final option is to abandon the home country application and not pursue patent protection.

The choice among these options depends on many factors. If the invention is completely or almost completely understood and its commercial potential known, then the decision as to in which countries to file can be made without much difficulty. Most pharmaceutical companies have listings of “filing groups” of countries that are used depending on the projected commercial potential for the invention. These filing groups may contain a few major countries up to a large number of countries, e.g., 50 to 100 countries or more. Each company develops its own set of filing groups based on numerous factors including costs, strength of protection in each country, the company’s markets, etc. Likewise, the selection of the filing group for each particular invention depends on factors such as type of invention, perceived commercial potential, projected market areas, and the like.

Alternatively, if the invention and its commercial potential are not fully understood, the applicant could abandon or abandon and refile. This process carries with it the danger that someone else may have filed a patent application between applicant’s priority date and the second priority date obtained through the refiling process. When this occurs, the applicant loses the rights to the invention in most countries. This can be especially dangerous in highly competitive areas in which many people are conducting research.

An alternate strategy is to file the foreign applications under the provisions of the PCT to obtain, an additional 18 months before the significant filing fees and cost of translations are incurred (see discussion under PCT, above).

Even after the 12-month priority period has passed, the applicant may still file patent applications, provided there has been no publication or public use of his invention. Applications filed in most countries including the EPO and PCT are published 18 months after the priority date. The United States will begin publishing applications filed on or after November 29, 2000. If the application has not been published and the applicant has not published in any scientific journals, he or she can still file in a country and obtain a patent. This is called a nonconvention filing

because the applicant does not claim rights back to his first priority date. Therefore, if new information about the commercial potential of the invention becomes available between the 12th and 18th months, one should always review it carefully and decide whether nonconvention applications should be filed.

Examination of the Application

Once an application has been filed, each patent office will examine it before granting a patent. The completeness of this examination differs from country to country. In some countries, it is a matter of merely verifying that the application has all the proper formal papers required under the laws and regulations of that country. Other countries carry out a rigorous examination as to the patentability of the invention in addition to the formal matters of proper documents. The United States, Japanese, and European patent offices examine patent applications for all requirements of patentability. In the United States, applications filed on or after May 29, 2000, must be granted within 3 years. If it is not, a patent term adjustment is available, provided the applicant has followed all procedures in a timely manner. Currently, the EPO starts the examination process approximately 2 to 3 years after the application is filed. Japan uses a deferred examination process. An application filed in the Japanese Patent Office remains dormant until the applicant requests the patent office to examine it. It can be deferred up to 7 years from the filing date. Once requested, the examination process in Japan normally takes 2 to 3 years to complete. On occasion, this process can take significantly longer because Japan has a pregrant opposition system. This means that once the patent office makes a determination to grant an application, it is published, and within 90 days of that publication date, anyone may file an opposition to the grant. If this occurs, a lengthy proceeding can ensue, possibly deferring the patent grant for many years.

Content of a Patent Application

Each country sets forth the requirements for a patent application through its laws and regulations. The United States does this through Section 112 of the Patent Law. This section specifies that the application must contain two parts: the specification and the claims. The requirements of the specification are set forth in the first paragraph of Section 112, as follows:

The specification shall contain a written description of the invention and the manner and process of

making and using it in such full, clear, concise and exact terms as to enable any person skilled in the art to which it pertains or with which it is most nearly connected to make and use the same and shall set forth the best mode contemplated by the inventor of carrying out his invention. To summarize, there are three requirements: a written description, an enabling disclosure, and the best mode. A written description and an enabling disclosure are universal requirements. However, the best mode requirement is distinctive to the U.S. patent system and is one that causes much debate among patent administrators. The requirement is based on the theory that applicants should not receive the privileges of patent protection if they have not disclosed the best methods of making and using the invention known to them at the time the patent application is filed. If applicants fail to disclose the best mode, even unintentionally, the patent can be held invalid.

Based on these disclosure requirements, the application normally contains the following:

1. Abstract
2. Summary of the background needed to understand the invention
3. Summary of the invention
4. Detailed description of how to practice the invention including appropriate examples and drawings.

The second paragraph of Section 112 requires that applicants point out and distinctly define the invention with a set of claims. Up to this point, a patent application has been a scientific article that teaches other people in the same field how to make and use the invention. This is no different than a scientific journal article. The claims, however, set forth what the applicant considers to be the invention for which patent protection is being sought. During the examination process, the claims may be modified to overcome objections. Therefore, one often finds, as a result of the examination process, the allowed claims of a granted patent often define less subject matter than is disclosed in the specification. Because the claims define the subject matter protected by the patent, when asked a question regarding infringement, a patent attorney will turn immediately to the claims to begin an analysis rather than to the description in the specification.

OWNERSHIP

Patents are property whose ownership may be governed law, contract, or by statutory provision. In many employer-

employee relationships, the employee has signed a contract of employment. This contract states that the employer owns all inventions made by the employee. In some countries, most notably Germany, there are elaborate statutory provisions for compensation of inventors by the employer. In all countries except the United States, the owner of the patent rights may file the patent application. Historically, the U.S. system has been based on rewarding the inventor and thus requires that the inventor apply for the patent. If the inventor is required by a contract of employment to assign the inventions to the employer, the U.S. application is made in the inventor's name, and an assignment noting the transfer of rights to the employer is recorded in the patent office.

INVENTORSHIP

In most of the world, inventorship of a patent may be relevant as to who owns the rights but it is not relevant to the validity of the patent. In fact, in some countries the inventor may never be mentioned or even appear on the patent. Again, the one important exception is the United States, where, as noted above, the inventor or inventors must file the patent application. If the wrong inventor or inventors intentionally apply for the patent, grounds for declaring the U.S. patent invalid are raised. Therefore, the proper inventors of the claimed invention are always determined according to the requirements of U.S. law.

It must be remembered that inventorship is different from authorship. Inventorship is based on legal requirements and must be strictly followed, whereas authorship is more arbitrary. The determination of inventorship is based on first inspecting the invention and determining what person or persons made an "inventive" contribution to the conception and reduction to practice of this invention. Conception is the mental steps taken to develop the invention. Reduction to practice is the physical process of taking the idea to the completed working invention. When two or more inventors (joint inventors) are involved, each must contribute to the claimed invention, but each is not required to have made a contribution to each claim of the patent.

Inventorship determination is not always straightforward and simple in today's research environment. However, to make these correct determinations, certain questions are asked. Did the person do only routine work or experiments as directed by another, or did he or she contribute something more? Was the invention completed because of the specific activity of this person? Did this person proceed beyond specific directions? In today's

modern pharmaceutical research atmosphere, in which teams are involved in the discovery and development processes, the patent attorney may find the determination of the correct inventorship a very difficult aspect in the preparation of a patent application. In a 1972 decision, U.S. District Court Judge Newcomer made the following observation:

The exact parameters of what constitutes joint inventorship are quite difficult to define. It is one of the muddiest concepts in the muddy metaphysics of patent law.

WHEN TWO OR MORE GROUPS MAKE THE SAME INVENTION

Sometimes two or more applicants make the same invention, but only one patent can be granted. The question is who receives the patent grant. In all countries except the United States, the first to file a patent application is granted the patent. In the United States, the patent is granted to the first to make the invention.

The first inventor is determined by a special administrative proceeding in the patent office called an interference. Evidence is presented by each applicant as to their earliest dates of conception and reduction to practice. Before January 1, 1996, only activities carried out in the United States could be used in these proofs. Now activities carried out in any country that is a member of the World Trade Organization can be used to prove when the invention was made.

In an interference, the proof requirements are very important. Activities or evidence given by the inventor must be collaborated in some manner. This is best accomplished through evidence from noninventors, although other forms of evidence have been used successfully in some cases. For this reason, research organizations have policies and procedures governing notebook recordkeeping in their laboratories.

Interferences are very complex and expensive proceedings that can delay the patent grant for many years. Fortunately, only less than 0.5% of all U.S. applications are involved in an interference.

LENGTH OF PATENT PROTECTION

The term of a patent grant is defined by the laws of each country, varying generally from 15 to 20 years. In some developing countries, patent terms are much shorter and

are of very little value to the pharmaceutical industry because the patent expires before the product can be marketed. Recently most countries, including the United States, have adopted a standard patent life of 20 years from the filing date. The United States, which until June, 1995, had a term of 17 years from the patent grant date, has recently enacted additional laws to restore any of the 20-year term lost because of delays in the patent office. Japanese patents have a 15-year term from the date of grant or 20 years from the date of filing, whichever is shorter.

In the pharmaceutical industry, the term of patent life is a very important factor. Because patents are filed very early in the life cycle of a new pharmaceutical product and much premarketing testing is needed before the health authorities will permit public sale of a product, a large portion of patent life is lost. Often, the term "effective patent life" for pharmaceutical products is used. Studies by the Pharmaceutical Research and Manufacturers of America have shown that effective patent life for pharmaceutical products averaged 15 years in the early 1960s and declined to 8 years in the early 1980s. Studies in Japan and Great Britain gave similar results. In recent years, the laws of many important countries have been changed to provide for the recapture of some of this lost patent life through patent term extension provisions.

Patent Term Extensions

Before 1980, in some countries, mainly those that were formerly part of the British Commonwealth, patent extensions were obtainable on petition at the end of the patent life. For a petition to be granted, the patent owner was required to show inability during the normal life of the patent to receive sufficient remuneration from the use of the patented invention. Under this system, patent extensions of 4 to 10 years could be obtained based on the evidence presented.

In 1984, the United States passed the first patent term restoration statute as part of the Drug Price Competition and Patent Term Restoration Act of 1984 (often referred to as the Waxman-Hatch Act). This was a significant law for the total pharmaceutical industry because it contained provisions important to both the research-based and the generic sections of the industry. Under this act, generic pharmaceutical companies were allowed to file abbreviated new drug applications (ANDA) and to do the testing required to submit an ANDA before the patent expired without being liable for patent infringement. The second part provided for the innovator of a new pharmaceutical product to receive up to 5 years of patent extension based on the time required to receive marketing approval from the Food and Drug Administration.

The extension can provide effective patent life for the product no longer than 14 years from the date of marketing approval.

Other countries have followed the U.S. lead regarding patent term extension. Japan enacted a provision effective January 1, 1986, whereby patents covering pharmaceutical products could be extended for up to 5 years. The Japanese provisions differ from the U.S. law in several ways. First, more than one patent can be extended for each product. Also, the Japanese law requires that the patent be granted 2 years before health authority approval of the product. Korea has enacted a patent term extension law very similar to that in the Japanese system. Australia has replaced its “lack of remuneration” system with a system based on regulatory delay.

Effective on January 1, 1993, Supplementary Protection Certificates (SPC), a system of providing extended protection for pharmaceutical products, was created by the European Community (EC). Such certificates do not actually extend the patent per se but confers protection for the product covered by the granted marketing approval (MA) and any use of the product as a pharmaceutical product for humans or animals. If more than one patent protects the product, the owner must select only one patent to be the basis for the SPC. SPCs are granted by individual national patent offices and come into effect only after the normal patent term expires. The duration of the SPC is equal to the time from the patent filing date to first MA in the EC, minus 5 years, subject to the limitations that the SPC cannot be effective for more than 5 years or provide protection for more than 15 years from the date of first MA in the EC.

The patent owner must request the SPC in the patent office of each country EC within 6 months of the first MA in that country or within 6 months of the patent grant date if it occurs after the first MA in that country. The SPC will be granted if, at the time the application is filed, 1) the patent has not expired; 2) an MA has been granted; 3) the product has not previously been the subject of an SPC; and 4) the MA is the first authorization to market the product.

The regulations allowed Spain and Greece to delay accepting the SPC system for 5 years. In addition, transitional provisions were adopted that allowed each country to choose to allow SPCs for products whose first MA was granted after January 1, 1982, June 1, 1985, or January 1, 1988.

MAINTAINING AND ENFORCING PATENTS

After a patent is granted, the owner must pay fees to keep it in force and may have to defend it from challenges to its validity and/or enforce it against infringers.

Maintenance Fees

In most countries, a patent does not automatically stay in force from the day it is granted until the end of its life. Most countries require payment of fees, referred to as renewal or maintenance fees, to keep the patent in force. In most countries, these fees are paid on an annual basis. Until 1980, the United States was a notable exception. However, in 1980 the United States modified its patent laws to require that fees be paid at three different time periods during the life of the patent. Specifically, renewal fees must be paid at 3.5, 7.5, and 11.5 years from the date the patent is granted. Although renewal fees vary from country to country, it is universal that the fees increase over the life of the patent. For example, the U.S. fees in 2000 are \$930, \$1870, and \$2820 for the three periods, whereas in Germany fees begin at approximately 150 DM and increase to 3500 DM for the 20th year. If the owner of the patent knows that it has no value to himself or others, he or she will generally stop paying the fees and allow the patent to lapse. Maintenance fees on a portfolio of patents can become very expensive, therefore, most companies have a program of regular review of their patent portfolio. Patents, that are no longer of value to them are lapsed.

Invalidation

Once a patent is granted, the patent owner is not guaranteed that it is valid. Challenges to the validity of the patent again vary from country to country, depending on the specific patent law of each country.

In the United States, the patent law specifically provides that a granted patent carries with it a presumption of validity. Until 1980, the validity of a patent could be challenged only in a federal court as part of an infringement action or by suit for declaratory judgment of invalidity. This latter action could only be initiated by a party who was threatened by the patent owner so that the requisite legal dispute actually existed between the parties. In 1980, the patent law was amended to allow any person to file a request in the patent office for re-examination of a U.S. patent based on new prior art. The patent office studies the request and determines whether to grant reexamination. This procedure is not used very often because the third party requestor has little opportunity to fully present its views. On November 29, 1999, a new reexamination law was passed that applies to patents originally filed after that date, which allows for greater participation by the third party.

In Europe, challenges to the validity of patents must be made in each individual country unless a central opposition has been made to a European patent (see above).

PATENT INFRINGEMENT

A patent is infringed when someone makes uses or sells the claimed invention without the permission of the patent owner. When this occurs, the patent owner can take legal action against the party.

In the United States, this is a civil action brought in the federal courts. The specific federal district court in which a patent owner can sue an infringer is governed by federal law. Patent litigation is very expensive and time-consuming. For this reason, it is not entered into without careful consideration of the consequences and analysis of all options available. In recent years, various alternative dispute-resolution proceedings have been used more often.

Because patents are limited in their effect in a specific country, a company with a pioneering drug may find itself suing patent infringers in a number of other countries. Usually these actions are in countries where the patent system is not as strong as that in the United States and the major European countries. The direct costs of patent litigation are usually lower outside the United States, but the time requirements can be just as extensive.

Patents to compounds or pharmaceutical compositions are infringed by their sale or use in the country of issuance. Patents to processes for the preparation of a compound cause a different problem. There is no direct infringement if the compound is made by the process in a country without patent protection and then imported into the country where the process is patented. However, the laws of many countries specify that the sale or use of compounds made directly by a patented process is an infringement of the process patent. In most cases, “directly” means the final step to prepare the compound. Such protection was not available in the United States until 1986, when the patent laws were amended. The amendment also has a provision whereby a party can ask the producer of a compound for a list of any U.S. process patents that are owned or licensed.

REGULATORY EXCLUSIVITY AND ORPHAN DRUGS

Although patents are the main defense against generic copying in the pharmaceutical industry, another important form of protection that has developed in recent years relates to the data generated by the originator of a product in support of the marketing approval application. Specifically, valuable periods of so-called regulatory exclusivity have become available in the United States,

Europe, and Japan. In addition, in the United States, the Orphan Drug Act has provided a special kind of regulatory exclusivity.

Regulatory Exclusivity

The interests of public safety and avoidance of unnecessary animal experimentation make it desirable that licensing authorities be able to cross-refer the originators file to establish safety and efficacy of generic versions of a product. Applications for marketing authorizations that rely on cross-referral to the originators full regulatory submission are generally known as abridged regulatory applications. Regulatory exclusivity is a temporary prohibition on cross-referral to the originator’s data without the originator’s consent. After a specified time, as detailed below, the originator cannot object to the cross-referral. Regulatory exclusivity is acquired rather than applied for by the originating drug manufacturer, and no certificate or other documentation is issued for the exclusivity period.

In 1980, Japan became the first country to have a regulatory exclusivity provision. The period is 6 years for new products, new combination products, or different routes of administration. For other modifications, such as a new indication or a new dosage regimen, the period of exclusivity is 4 years. If second applicants do their own complete safety and efficacy studies, these periods of exclusivity do not apply.

In the United States, these regulatory exclusivity rights are part of the Waxman-Hatch Act. The law provides that no abbreviated new drug application (ANDA) can be submitted for a generic equivalent for a new chemical entity (NCE) until 5 years after the approval date for the NCE. If the ANDA applicant certifies that the patent covering the NCE is invalid or not infringed, the period is 4 years. If a NCE is not involved or a pioneering supplemental NDA is approved,

Table 3 European regulatory exclusivity

10 Years	6 Years
United Kingdom	Denmark
Austria	Finland
France	Greece
Germany	Ireland
Belgium	Luxembourg
Holland	Portugal
Italy	Spain
Sweden	

a 3-year period exists before an ANDA can *become effective*. Thus, for non-NCEs, the regulatory period is reduced to 3 years. For a NCE the 5-year period is for *submission* of an ANDA, and so the FDA processing time would extend this exclusivity period.

Another interesting part of this law is that if a generic drug manufacturer challenges a patent and is successful, it is rewarded with a 6-month period during which no other generic products will be approved.

In Europe, regulatory exclusivity is more complex. More specifically, the countries may choose between a 10-year or 6-year period. According to European Community Directive 87/21, the national states can protect pharmaceutical products for 6 or 10 years from first marketing approval in the European Community. An exception to this is biotech products for which a 10-year period applies for all European countries. The countries that have chosen 10 or 6 years are presented in Table 3.

Orphan Drugs

Drugs that are used for treating rare diseases or conditions are called orphan drugs. The U.S. Orphan Drug Act provides that the FDA may not approve another application within 7 years of approval of the first unless the originator cannot assure availability to meet the needs of patients. This law was amended in 1985 to apply to patented as well as nonpatented drugs. The requirements to be recognized as an orphan drug that are 1) the disease affects fewer than 200,000 persons in the United States, or

2) recovery of the R&D costs from U.S. sales is unlikely. A request must be made to the FDA to obtain orphan drug status. The determination of eligibility is made as of the date of the request. This 7-year period of marketing exclusivity applies only to the individual uses of the compound or product and not to the compound itself.

In Japan, a law was introduced in October 1993 providing benefits for designated compounds including an accelerated examination, a 10-year rather than 5-year regulatory exclusivity period, and tax benefits. The conditions for orphan drug status are that the drug must be for the treatment of diseases with fewer than 50,000 patients in Japan and clinical trials essential to development for that use.

There are no specific orphan drug regulations in the EU. Other countries do not have exclusivity for orphan drugs at this time; however, provisions exist in some countries for speedier approval.

PATENTS—UNITED STATES PERSPECTIVE

Lorie Ann Morgan

GlaxoSmithKline, Research Triangle Park, North Carolina, U.S.A.

Jeffrey Tidwell

University of North Carolina, Chapel Hill, North Carolina, U.S.A.

INTRODUCTION

The importance of pharmaceutical patents has increased with the dramatic growth of the generic pharmaceutical industry in the United States and the resulting competition between the research-based pharmaceutical industry and the generic pharmaceutical industry. The research-based pharmaceutical industry provides a continuing supply of new and better pharmaceuticals to treat illness and improve lifestyle. The generic pharmaceutical industry, on the other hand, strives to provide lower-cost generic alternatives to already approved drugs. Patents provide the research-based pharmaceutical industry with an opportunity to recoup the extensive investment costs involved in providing new and better pharmaceuticals to the public. At the same time, patents restrict the generic pharmaceutical industry's ability to obtain approval for competing generic drugs. While a patent claiming the drug is in force, the generic pharmaceutical manufacturer is precluded from conducting infringing activities. The balance between the need for extensive Food and Drug Administration (FDA) review and approval of generic drugs and the need to preserve the enforceability of patents protecting newly developed drugs and provide incentives for further research and development of new drugs prompted the Hatch–Waxman Amendments in 1984 (Drug Price Competition and Patent Term Restoration Act of 1984).

INNOVATOR PATENTS

Types of Patent Claims

Pharmaceutical companies spend billions of dollars on research and development programs each year in an effort to discover and develop innovative new medicines. As such, protection of these novel drugs and new technology developed during the research process from outside competitors is of paramount importance. The patent laws of the United States provide a mechanism by which

research-based pharmaceutical companies can protect their inventions and commercialize them exclusively for a term of 20 years. When applying for a patent, an inventor sets forth the subject matter to be protected at the end of the patent specification in the claims. The claims of the patent determine the scope of protection during the 20-year exclusivity period.

Patentable subject matter is "... any new and useful process, machine, manufacture, or composition of matter, or any new and useful improvement thereof ..." (1). Patent laws provide that patents may be granted only for inventions that are deemed to be "new and useful." These requirements exclude pharmaceutical inventions that have not been shown to be reasonably safe and effective and chemical compounds that have no use except as intermediates for additional research. However, some special considerations have traditionally been applied in the case of chemical compounds, particularly those possessing therapeutic or pharmacological activity. A compound that is useful as an intermediate for the manufacture of a pharmacologically active compound may be claimed and afforded patent protection because it satisfies the utility requirement and is considered to be "useful." Further, a compound need not show therapeutic utility in humans to meet the utility requirement of patentability; pharmacological activity in animals or in vitro activity is considered sufficient in some cases. If the patent application purports to claim the use of a compound for the treatment of humans, the inventor must show that the compound is both safe and effective in humans.

Multiple patents may be issued that provide protection for the same new drug product because a single invention may be claimed in a number of different ways. For example, a patent may claim the compound itself, a novel use for the compound in treating disease, and a method for preparing and administering the compound.

Composition of matter

The most expansive protection is afforded by claims that present the particular novel product or drug compound

itself. Claims to specific chemical entities permit the innovator to exclude others from making, using, selling, offering for sale, or importing the drug compound into the United States regardless of the purpose for doing so and regardless of the formulation into which the drug is included.

Composition-of-matter claims can include claims to small organic compounds that may be useful as drug candidates as well as claims to more complex biomolecules. For example, a composition-of-matter claim may encompass claims to proteins, plasmids, pieces of DNA or RNA, and pharmacological receptors.

Another area of particular importance to the pharmaceutical industry of late is the patentability of living organisms. The last several years have seen a dramatic increase in the pace of biological research and technology. As a result, the courts have had to deal with the question of whether or not manmade living organisms qualify as patentable subject matter. Although the courts struggled with this issue, it is now fairly settled that manmade living organisms, such as genetically engineered animals, biologically pure cultures, and genetically engineered microorganisms, are patentable subject matter.

Natural products

An area of great importance to the pharmaceutical industry in particular relates to the patentability of natural products for use in treating disease. The last several decades have witnessed a dramatic increase in the search for compounds from natural sources, such as plants, for the treatment of human disease. It is established law that natural products are considered to exist in the “state of nature” and are not considered novel. Therefore, natural products generally cannot be claimed as a patentable composition of matter. This is true even if the natural product is isolated by novel means or is tested against novel drug targets. However, there are two ways in which natural products may be patentable. First, it is possible to obtain a method-of-use patent involving a natural product as it relates to novel biological or pharmacological activity. Second, it is possible to obtain composition-of-matter coverage for synthetic analogs of natural products because they are not considered to exist in the state of nature. This is of paramount importance because many new drugs are closely related, synthetic analogs of natural products.

Method claims

There are two types of method claims: method-of-making (or process) claims and method-of-using claims. An inventor may protect a new drug by claims directed toward the method of synthesizing the compound. Process claims provide the inventor with the right to exclude others

from using the claimed methods to prepare a chemical compound. In addition, the Process Patent Amendment Act (2), discussed below, provides the inventor with the power to prevent others from importing into the United States any compound or formulation thereof using the methods claimed in the patent. However, a process patent does not prevent others from making or using the compound or formulation when it is prepared by a method other than that claimed. Therefore, although method claims are valuable in serving to protect drug products, they are much more limited in scope than compound per se claims.

Another area of importance in terms of patenting methods of making relates to novel methods developed for the synthesis of chemical or biological target molecules. The last decade has witnessed an explosion of innovation in the areas of biochemistry and combinatorial chemistry, particularly as they apply to drug discovery and development. New methods of generating vast numbers of biological molecules, such as DNA and proteins, as well as new technology used to prepare chemical “libraries” for use in screening new drug candidates have exponentially increased the number of patent applications directed toward these applications. It is generally established that these new types of technology are patentable subject matter and as such can be patented.

The second type of method-of-use claims relates to methods of using the invention. In terms of pharmaceuticals, method-of-use claims typically relate to the use of a particular drug in the treatment of specific diseases or conditions. FDA approval of a new drug is linked to specific therapeutic uses, and therefore these types of method claims provide important protection for the innovator. These claims are important because they provide patent protection that is in addition to any composition-of-matter claims that may be applicable. Method-of-treatment claims are particularly important for compounds that are already subject to composition-of-matter claims or for which composition-of-matter claims are not available. For example, an inventor may discover that a previously known compound possesses unreported and unexpected anti-inflammatory properties. The inventor may not obtain composition-of-matter protection for the compound itself because the compound is contained in the literature and therefore does not meet the novelty requirement for patentability. However, the inventor may instead obtain a method-of-use claim based on the unexpected anti-inflammatory properties because a compound’s unexpected properties may be enough to support patentability.

Chemical intermediates

Generally, novel chemical compounds that are intermediates for the preparation of other chemical compounds of

unknown utility are not considered patentable subject matter. However, if the intermediate is used to produce a compound that is known to be useful, then the utility requirement is satisfied, and a patent may be obtained for that intermediate. Claims directed toward chemical intermediates are particularly valuable when they cover stable intermediates that are critical to the only commercially feasible synthetic route to the drug.

Formulations

Still further protection may be afforded by claims that cite a specific formulation of a drug product. Formulation claims allow the inventor to exclude others from making, using, selling, offering for sale, or importing the claimed formulation into the United States. They represent an important opportunity for expanding the patent portfolio protecting a drug, in part because FDA approval for a drug is specific to the formulation containing the drug. Formulation claims may not provide exclusivity to the innovator, but formulation claims expiring after the expiry of compound claims may be a useful tool in maintaining maximum market share for as long as possible.

Reach-through claims

Another recent development in pharmaceutical patents involves so-called reach-through claims. Reach-through claims seek to cover, for example, drugs used for the treatment of conditions that are identified through a particular drug-screening assay without actually specifying the drugs that are covered. These claims, once granted, are exploited through licensing to seek royalties based on sales of products that are developed in part through use of the patented research tool assay. This particular strategy has become a favorite among smaller biotechnology companies that have expended a large portion of their capital in developing new technologies or materials. Several well known examples of reach-through claims are licenses under the Cohen-Boyer patent on basic recombinant DNA techniques and the patents on the Harvard recombinant onco-mouse and Roche polymerase chain reaction. The status of reach-through claims has yet to be determined in the courts.

Compound claims directed toward the drug compound generally afford the broadest scope of patent protection against competitors. However, no single type of claim can afford the best patent protection. The best protection against competitors includes a portfolio of patents, each of which is directed toward a different aspect of the drug. For example, an inventor may obtain a patent for composition of matter that covers the chemical compound itself, another for its method of synthesis, several relating to different formulations, and still others to different therapeutic uses

of the drug. Typically, one seeks to protect new drugs with a broad portfolio of patents to make it difficult for competitors to design around any one patent. As such, it is essential that generic drug manufacturers identify the full range of patents surrounding a particular product to avoid liability for patent infringement.

EXCLUSIVITY FOR THE INNOVATOR

Patent Exclusivity for the Innovator

Patent term

Before June 8, 1995, U.S. patents expired 17 years from the date the patent was issued. However, changes were made in the U.S. patent laws in 1994, in accordance with the Uruguay Round Agreements Act (URAA). The URAA governs the specific date on which a granted U.S. patent expires, which is 20 years from the filing date of the application (3). The changes enacted in response to the URAA were not made to extend patent terms, but to harmonize the term provisions of U.S. patent law with those of other, leading trading partners. In the case of applications filed as continuations or divisionals of previously filed applications, the filing date of the first U.S. priority application is the date from which the 20-year term is measured. For international applications filed under the Patent Cooperation Treaty (PCT), the 20-year term is measured from the filing date of the international application designating the U.S. Foreign national priority (under 35 U.S.C. §119) is not considered in the calculation of the 20-year term. For example, an application filed on June 10, 1995, that does not assert any claim priority to an earlier U.S. application would have an expiration date of June 10, 2015. However, an application filed on January 23, 1997, that is a continuation of an application filed on June 10, 1995, and that claims priority to that date, would have an expiration date of June 10, 2015. The expiration date is the same if the application claims a priority to a previous foreign application.

For those patents currently in force and those that will issue from applications filed before June 8, 1995, the patent term is the longer of either 17 years from the issue date or 20 years from the first U.S. filing date. It is possible for the terms of patents that have already been issued to be extended if they fall within the transition period. The expiration date of an issued patent is extended if the date that is 20 years from the first U.S. filing date is later than the date that is 17 years from the patent issue date. Consequently, any patent that required less than 3 years of prosecution from the first U.S. filing date receives an

extension of term by virtue of the URAA 20-year term provisions.

A U.S. patent application filed on March 1, 1992, and issued on April 1, 1994, would have an expiration date calculated under the provisions for the transition period. The expiration date calculated 17 years from issue would be April 1, 2011. The expiration date calculated 20 years from the first U.S. filing would be March 1, 2012. Because the patent term as calculated 20 years from filing is longer, the expiration date of this patent would be extended to March 1, 2012; thus, the patent will receive an extension of term equal to 11 months. The extension is granted despite the fact that the patent was issued before the passage of the URAA provisions.

In addition to these term provisions, in 1999 Congress passed the Patent Term Guarantee Act as part of the American Inventors Protection Act. The Patent Term Guarantee Act, which will go into effect on May 29, 2000, provides that patent terms will be extended to compensate for certain processing delays in the U.S. Patent and Trademark Office and for delays in the prosecution of applications pending for more than three years. Also, extensions are available for delays in issuance of a patent attributable to interference proceedings, secrecy orders, and appellate review. Patent applicants that demonstrate due diligence in the prosecution of their application are guaranteed a minimum 17-year patent term. The act applies only to applications filed on or after the date of enactment, which is May 29, 2000.

Patent-term restoration

Patents claiming a pharmaceutical product, therapeutic uses for a pharmaceutical product, or methods of making a pharmaceutical product may also be eligible for an extension of patent term under the Patent Term Restoration Act (Hatch–Waxman Amendments) (4). Its purpose is to allow the innovator to recover valuable patent term lost during the regulatory review process. The innovator's patented product cannot be commercialized until regulatory approval is obtained. As a result, the innovator is not permitted to reap the benefits of its patent exclusivity until the lengthy approval process is complete. To be eligible for a patent term extension, the patent must claim a product or method of using or manufacturing the product, the patent must not have been previously extended, the application for patent term extension must be submitted within 60 days of approval, the product covered by the patent must have been subject to regulatory review before commercial marketing and use, the approved commercial marketing and use of the product must be the first commercial marketing or use under which the regulatory review period occurred, the patent must not have expired, and no other

patent term must have been extended based on the same regulatory review period (5). Although many patents may cover a single product, only one patent per product may be extended under these provisions, and the extension of the patent term applies to those claims that cover the product receiving regulatory approval.

The length of the patent term extension is directly related to the length of the regulatory review period. The period of extension is calculated by adding half of the length of the testing (IND) period to the length of the approval (NDA) period and subtracting any part of the period that occurred before the issuance of the patent and any part of the period in which the applicant did not act with due diligence (6). The maximum available term extension is 5 years (7). The total patent term, after the extension period, cannot exceed 14 years after the date of approval by the FDA (8). In other words, the patent expiry date, after the addition of the extension period, must be not later than 14 years after the date of FDA approval.

The passage of the URAA, adopting a 20-year patent term, raised questions in circumstances in which a single patent was eligible for a longer term under the URAA 20-year term provisions (hereinafter “URAA extension”) and had also received an extension under the Patent Term Restoration Act (hereinafter “Section 156 extension”). The most important question was whether a patentee could reap the benefit of both extensions by adding the URAA extension and the Section 156 extension to prolong the period of patent exclusivity. The Federal Circuit Court of Appeal resolved this issue in *Merck & Co. v. Kessler* (9). In that case, the Court held that the expiration date of a patent having both a URAA and a Section 156 extension is 20 years from filing plus the Section 156 extension, unless the patent is in force on July 8, 1995, solely by virtue of the Section 156 extension. In other words, the foregoing rule applies, except when the patent's 17-year term had expired before June 8, 1995, and the patent is only enforceable by virtue of the Patent Term Restoration Act. Unfortunately, the Federal Circuit Court did not provide a calculation for the expiration date of patents that are in force on June 8, 1995, only because of the Patent Term Restoration Act. However, it would seem that few patents are affected by this omission.

FDA Exclusivity

In addition to patent exclusivity, an innovator may help preserve its market share for a new drug through FDA exclusivity. FDA exclusivity does not guarantee the innovator an exclusive right to market the drug, but it does operate to block approval of ANDAs for generic versions of the drug. FDA exclusivity does not prevent

a manufacturer from developing and obtaining approval for a new formulation using the same active ingredient by filing a new drug application (NDA).

The length of the FDA exclusivity period depends on the nature of the new drug developed by the innovator. The statute provides that no ANDA may be submitted for a drug (i.e., new chemical entity) approved after September 24, 1984, until the expiration of 5 years from the date that the innovator received first approval, with one exception (10). An ANDA may be submitted before the expiration of 5 years if it contains a certification of patent invalidity or noninfringement (11). A new NDA for a previously approved drug, if supported by new clinical investigations, enjoys a 3-year exclusivity period during which no new ANDAs may be approved based on the new NDA (12). Supplemental NDAs supported by new clinical investigations also enjoy a 3-year period of exclusivity (13).

The Food and Drug Administration Modernization Act (FDAMA) was passed in 1998, providing for an additional period of exclusivity based on clinical trials conducted in pediatric patients (hereinafter “pediatric exclusivity”). The award of exclusivity is provided as an incentive to the industry to conduct pediatric studies that are requested, but not required, by the FDA. Pediatric exclusivity provides an additional 6 months of exclusivity at the end of any remaining exclusivity or patent life of any patents covering the approved product (14). To be eligible for pediatric exclusivity, the innovator must receive from the FDA a written request to conduct pediatric studies, submit study reports after receipt of the written request, and meet the conditions of the written request. The applicant may request that the FDA issue the necessary written request to qualify for pediatric exclusivity. The award of exclusivity attaches not only to the product tested in the pediatric studies but to any formulations, dosage forms, and indications for products having existing exclusivity or patent life that contain the same active ingredient.

Notice to Generic Manufacturers of Innovator’s Exclusivity

The FDA provides notice of the innovator’s FDA and patent exclusivity by publishing information regarding exclusivity in the FDA Approved Drugs Product List (the “Orange Book”). The Patent and Exclusivity Appendix to the list of approved products provides details regarding the expiry dates of all types of FDA exclusivity (including pediatric exclusivity) and the expiry dates of patents for each approved product.

The patent information provided in the Orange Book for an approved product is obtained from the innovator.

Innovators are charged with the duty to notify the FDA of the patent number and expiration date of any patent that claims the drug (i.e., the active ingredient or the formulation) or its approved therapeutic use (15). The innovator must update the patent information for an approved product in an appropriate and timely manner as new patents covering the approved product are granted. The innovator must also update the patent information to account for any patent term extension awarded. The submission of this patent information to the FDA ensures that generic drug manufacturers are on notice of the innovator’s patent rights and invokes certain innovator rights, discussed below, with respect to notification of an ANDA filing by a generic drug manufacturer and infringement action based on ANDA filing. For these reasons, it is in the innovator’s best interest to provide patent information in a timely manner, and, for purposes of competing with the innovator, it is in the generic drug manufacturer’s best interest to be knowledgeable of the patent information provided in the Orange Book.

GENERIC COMPETITION

The ability of a generic pharmaceutical manufacturer to commercialize a generic version of an innovator’s product centers around two closely related issues: FDA marketing approval and the innovator’s patent portfolio. In addition to the requirements designed to establish that the generic drug is in fact equivalent to the approved innovator drug in terms of composition, manufacture, biological activity and labeling (16), the ANDA must also include a patent certification, also known as a paragraph i, ii, iii, or iv certification, regarding the nature of any patent exclusivity for the approved drug and its approved indications (17). The ANDA applicant must certify that in the opinion of the applicant and to the best of the applicant’s knowledge with respect to each patent that claims the approved drug or its approved therapeutic use:

- i. Patent information has not been filed;
- ii. The patent(s) has expired;
- iii. The date on which the patent(s) covering the approved drug will expire; or
- iv. The patent(s) covering the drug is invalid or will not be infringed by the manufacture, use, or sale of the generic drug for which approval is sought.

The paragraph (i) certification states that patent information for the approved drug on which the ANDA is based has not been filed according to the requirements of the statute. This paragraph applies when there are no patents

covering the approved product or its use or if the innovator has failed to properly list the patents covering the drug. It is very rare that no patents will exist for an approved drug, with the possible exception of very old drug products. This is because the investment required for an innovator to obtain marketing approval for a new drug is so great that it would not be feasible for an innovator to commercialize a new drug that lacked a significant period of patent exclusivity during which the innovator could recover the substantial costs of research and development. However, a paragraph (i) certification also applies when the innovator has failed to comply with the rules requiring the listing of all patents covering the approved drug. If the innovator failed to list the patents covering the approved product, and the ANDA applicant could establish that it was not aware of any unlisted patents that claimed the approved drug, the ANDA applicant would likely choose to include a paragraph (i) certification in the ANDA. An ANDA filed with a paragraph (i) certification may be approved effective immediately, barring any FDA exclusivity held by the innovator.

Under a paragraph (ii) certification, the generic drug manufacturer certifies that the patents covering the approved product have already expired. Typically, paragraph (ii) certifications are used only for older drug products because it is common for the ANDA to be filed before the actual expiry of the innovator's patents. An ANDA filed with a paragraph (ii) certification may be approved effective immediately, barring any FDA exclusivity held by the innovator.

Under a paragraph (iii) certification, the generic drug manufacturer certifies that the innovator patents will expire on a certain date and requests marketing approval as of that date. In this case, the FDA may grant tentative approval of the generic drug manufacturer's ANDA before the patent expires, but the generic drug manufacturer does not receive full approval and therefore cannot commercialize the generic product until after the patent expires.

Under a paragraph (iv) certification, the generic drug manufacturer certifies that the innovator patent(s) is either not infringed by the generic product or that the patent(s) is invalid or unenforceable. Paragraph (iv) certifications are discussed in more detail in the following section on infringement.

In this manner, the approval of an ANDA is, in part, dependent on the generic drug manufacturer avoiding infringement of the innovator's patents. The first step to avoiding infringement of the innovator's patents is to identify the particular patents that cover a particular approved product.

Identifying Patents Relating to a Drug

The Orange Book

There are several ways in which a generic pharmaceutical manufacturer can identify the extent of patent exclusivity on a product it wishes to produce. An innovator must submit to the FDA a list of patents that it believes covers the drug product, formulation, or specific therapeutic use of the new drug (18). The patents are subsequently published in the Orange Book. The patents to be listed must be submitted in a timely manner. Any patents directed toward the drug that might issue after the approval of the drug must be disclosed to the FDA within 60 days of issuance. This ensures that the FDA listing of patent exclusivity for a given approved drug is current. Although the FDA does not have the resources to police innovators to ensure compliance with the patent identification regulation, the courts have occasionally imposed a disincentive for failing to comply with the regulation. In particular, one court has determined that the innovator could not sue the ANDA applicant for infringement on the basis of filing the ANDA because the innovator did not list the patent in the Orange Book before filing the law suit (19). The rationale given by the court is that Congress intended that an ANDA applicant consult only the Orange Book to determine the existence of an applicable patent claiming the listed drug or a use of the listed drug.

The Orange Book is an appropriate starting place for the identification of patents claiming an approved drug, formulations of the approved drug, and therapeutic uses of the drug. However, innovators are not required to specify process patents in the Orange Book. As a result, the search for patents that may prohibit the commercialization of a generic form of the drug cannot be complete by merely referring to the Orange Book. For purposes of identifying relevant process patents relating to an approved drug, the Process Patent Amendment Act of 1988 requires the innovator to identify patents it considers relevant to a particular drug on receipt of a written request to do so.

Requests under the Process Patent Amendment Act

The Process Patent Amendment Act of 1988 encourages the generic pharmaceutical manufacturer to submit a request for disclosure of process patents relating to a particular drug to the innovator or patent holder (20). Making such a request is considered evidence of good faith on the part of the generic drug manufacturer in the event that litigation later ensues over the patent(s) (21). The request for disclosure must be in writing and be made to a person engaged in the manufacture of a product, asking for

identification of all process patents owned by or licensed to that person as of the time of the request that the person reasonably believes could be asserted to be infringed if the product is imported into or sold, offered for sale, or used in the United States without prior authorization (22). The request for disclosure must be made by a person regularly engaged in the United States in the sale of the same type of products as those manufactured by the party to whom the request is submitted (23). It must also be made before the first importation, sale, or offer for sale of the product by the generic pharmaceutical manufacturer (24). Finally, it should include a statement that any patents identified by the innovator will be submitted to the party who will manufacture or supply the drug and that the generic drug manufacturer will request from the supplier a written statement that none of the processes claimed by the patents is used in the manufacture of the generic drug (25).

After the request for disclosure is received, the patent owner must reply within a reasonable period to be considered to have acted in good faith. However, no reply is required if the products are marked with the process patent numbers before the request is received by the innovator (26).

The Orange Book and the Process Patent Amendment Act are appropriate avenues for identifying the patent exclusivity of an innovator with respect to a specific drug. However, before proceeding with the investment required for the regulatory approval of a generic drug, the pharmaceutical manufacturer should conduct an independent search of the patent literature to identify additional relevant patents. For example, parties other than the innovator may hold patents that affect or even block the ability to commercialize a generic drug. Patent holders other than the innovator are not subject to the same statutory requirements and, furthermore, may not be readily identifiable without an independent search of the patent literature.

PATENT ENFORCEMENT BY THE INNOVATOR

General Principles of Patent Infringement

Infringement is defined as the making, using, selling, offering for sale, or importation into the United States of any patented invention without the authority of the patent owner (27).

Liability for patent infringement only extends throughout the life of the patent. Once the patent term expires, the invention is in the public domain and may be made, used, sold, and/or imported freely. Infringement liability attaches regardless of the quantity or amount of the patented invention that is made, used, sold, offered for

sale, or imported. However, the quantity or amount of infringing products may be relevant in determining the damages to be awarded to the patent owner.

Infringement liability is limited territorially. Patent infringement of a U.S. patent arises only when the patented invention is practiced in the United States. The manufacture, use, or sale of the patented invention outside the United States cannot be prohibited by the patent owner, except to the extent that the patent owner also holds a patent in each of the countries where the invention is practiced.

One caveat to the foregoing is that anyone who, without the authority of the patent owner, imports a product into the United States that is prepared abroad by a process claimed in a U.S. patent infringes the U.S. process patent under the 1988 Process Patent Amendments Act (28). In other words, if an unlicensed party uses a process claimed in an unexpired U.S. patent to produce a product outside the United States and then imports that product, the party is liable for the infringement of the U.S. process patent. Thus, even though the patented process is being practiced outside the United States, the patent owner may recover damages for infringement of the process patent once the product produced by the claimed process is imported into the United States. However, the act also provides that a product will not be deemed to be made by the patented process if: 1) it is materially changed by subsequent processes; or 2) it becomes a trivial and nonessential component of another product. For example, see *Eli Lilly and Company v. American Cyanamid Company* (29) for a case concerning what constitutes a “material change” to a drug product under the applicable statute.

Standards for Proving Infringement

The issuance of a valid U.S. patent gives the patent holder the right to exclude others from making, using, selling, offering for sale, or importing the patented invention during the patent term (30). Anyone who makes, uses, sells, offers for sale, or imports the patented invention without the patent owner’s consent infringes the claims of that patent. A product may infringe a patent literally or under the Doctrine of Equivalents.

Literal infringement

To define literal infringement, the plain language of the patent claims must first be properly interpreted. This is accomplished by consideration of the ordinary meaning of the language of the claim, the patent specification, the prosecution history of the patent, and the other claims in the patent. The individual claim elements are interpreted based on the ordinary meaning of the terms used, unless it is clear from the patent specification that the inventor intended to

use a special meaning. The product or process in question is evaluated for infringement with respect to the properly interpreted claims, not the preferred embodiment set forth in the specification or any commercialized embodiment of the patented invention. Thus, with respect to claim interpretation, the words of the claims are interpreted without consideration of the product in question.

Literal infringement focuses on individual claim elements rather than on the invention as a whole. Whether a product infringes the claims of the patent depends on whether the product literally embodies each and every element of those claims (31). Each element of a claim is material and essential to the definition of the invention. If the product or process does not use even one element of the patent claim, it will not literally infringe the claims. However, the accused infringer usually cannot escape liability for literal infringement merely by adding elements that are not found in the patent claims if each element cited in the claims is found in the product or process under investigation.

Infringement under the Doctrine of Equivalents

Although the requirements of literal infringement may not be satisfied, infringement may still be found under the Doctrine of Equivalents. This doctrine is satisfied when the product in question contains elements identical or equivalent to each claimed element of the patented invention (32).

To determine whether this product possesses elements identical or equivalent to elements of the patented product, many factors may be considered. For example, if this product performs substantially the same overall function in substantially the same way, to obtain the same overall result as the claimed product, the conclusion that the element in question is equivalent is supported (33). However, this is not the only factor evaluated to analyze the doctrine of equivalents. In addition, known interchangeability of the elements used in the accused product compared with the elements of the claimed product by those skilled in the relevant art supports the conclusion that the element of the accused product is equivalent to the claimed product. On the other hand, evidence of lengthy efforts to design around the claims of the patent supports the conclusion that the accused product is not equivalent to the patented product.

The Doctrine of Equivalents has recently been severely restricted by the Court of Appeals for the Federal Circuit. In *Festo Corp. v. Shoketsu Kinzoku Kogyo Kabushiki Co., Ltd.* (33a) the Court held that amendments made to patent claims during prosecution of the patent application, for reasons related to patentability, foreclose the patent holder from subsequently proving infringement using the Doctrine

of Equivalents. Furthermore, patent applicants that amend claims during patent prosecution for unknown reasons are also precluded from relying on the Doctrine of Equivalents to prove infringement with respect to the amended claims.

Prosecution history estoppel

The basic effect of the doctrine of equivalents is to allow the patent owner to expand the scope of protection afforded by the literal language of the claims. However, the doctrine of equivalents does not allow the patent owner to expand the scope of the claims without restriction. The ability of the patent owner to expand the scope of the patent claims is restrained by the prior art and also by the doctrine of prosecution history estoppel.

The prior art limits the degree to which the claims may be interpreted because the claimed invention cannot be interpreted so broadly under the doctrine of equivalents as to encompass products that were known before the patent owner invented the claimed product. In other words, the claims may not be interpreted as broadly under the doctrine of equivalents as to read on the prior art.

The doctrine of prosecution history estoppel also limits the degree to which the claims may be interpreted under the doctrine of equivalents. The doctrine of prosecution history estoppel precludes the patent owner from interpreting the claims in a manner that would encompass, within the claim, subject matter that the patent owner surrendered during prosecution of the patent application to achieve issuance of the patent. Any subject matter that the patent owner surrendered during prosecution to obtain allowance of claims made in the application of the patent cannot be reclaimed under the doctrine of equivalents.

The fact that the accused infringer may have developed the accused product completely independently and without knowledge of the patent is irrelevant in the analysis of infringement liability. An accused infringer cannot escape liability by demonstrating that the accused product was developed wholly through independent research and development.

Invalidity as a Defense to Infringement

An important defense to infringement is that the patent in question is invalid. A patent, once issued, is presumed valid. However, occasionally patents are issued that are invalid for one or more reasons. The focus of the analysis of invalidity is on the mandates of 35 U.S.C. Sections 102 and 103, which set forth the conditions of patentability (although challenges under other sections can be raised as well). In particular, when a challenger presents evidence, such as a prior art reference, which is more pertinent than

that considered by the patent examiner during the prosecution of the patent application, the burden of proving invalidity is more easily met (34).

Under Section 102(a), a patent claim is invalid if the claimed product was known or used by others in the United States, or was patented or described in a printed publication in the United States or a foreign country before the product was invented by the patentee (35). To anticipate a claim under Section 102(a), the challenger must show that the claimed product was publicly available before it was invented by the innovator, thus establishing that the patent owner was not the first to invent the claimed invention.

According to Section 102(b), a patent claim is anticipated, and therefore is invalid, if the claimed invention has been patented or described in a printed publication, or has been on sale, more than 1 year before the effective filing date of the application from which the patent was issued (36). To anticipate the claim, a single prior art reference must show each element of the claimed invention arranged as set forth in the claim. However, in the appropriate setting, a secondary reference may be used to explain or demonstrate that a primary reference anticipates a patent claim inherently.

A patent claim may also be invalidated if the challenger shows that the patent does not cite the true inventor(s) (37). A patent must list only the names of those individuals who contributed to at least one element of one or more claims. If the patent includes additional individuals who are not inventors or if the patent fails to include one or more true inventors, and the error in the naming of inventors occurred with deceptive intent, the claim(s) may be invalidated.

Section 103 can be used to invalidate patent claims even when the claimed invention is not identically disclosed or described for purposes of Section 102, if the differences between the claimed invention and prior art are such that the claimed subject matter as a whole would have been obvious at the time the invention was made (38). A determination regarding validity under Section 103 must address the following factors (39):

1. The scope and content of the prior art.
2. Differences between the prior art and the claimed invention.
3. The level of ordinary skill in the pertinent art, and
4. Secondary considerations evidencing nonobviousness.

The secondary considerations include commercial success, long-felt need, failure of others, copying, praise by persons in the industry, departure from accepted principles, and widespread recognition in the art of the invention's significance.

Remedies for Patent Infringement

Several remedies are available for patent infringement. The patent owner may obtain an injunction preventing the accused infringer from continuing the unauthorized practice of the claimed invention (40). The preliminary injunction is an important remedy because it enables the patent owner to immediately stop the activities of the infringer without the necessity of first obtaining a judgment of infringement through a lengthy litigation process.

The patent owner may also obtain monetary damages from the infringer (41), being entitled to adequate compensation for the infringement. Monetary damages may be measured in different ways to determine the amount that the patent owner can recover. For example, monetary damages may be based on the profits lost by the patent owner as a result of the infringement. In any event, the damages for the patent owner will not be less than a reasonable royalty for the practice of the invention (42).

When the infringement is shown to be willful or intentional, the patent owner may recover an increased monetary award of up to three times the amount of monetary damages shown, plus attorney's fees (43).

Infringement Exemptions for Generic Pharmaceutical Manufacturers under Hatch–Waxman Provisions

The Hatch–Waxman provisions were enacted to strike a balance between the competing interests of protecting the innovation of new drugs and providing an incentive for continued research and development of new drugs versus providing lower cost generic alternatives. To permit generic pharmaceutical manufacturers to begin the testing involved in obtaining FDA approval for a generic product, the Hatch–Waxman Act exempts the generic pharmaceutical manufacturer from patent infringement liability for certain activities. Under the Hatch–Waxman Act, it is not an act of infringement for a generic pharmaceutical manufacturer to make, use, sell, offer for sale, or import into the United States a patented drug if the act of doing so is reasonably related to the development and filing of an application for federal regulatory approval (e.g., FDA approval) (44). This exemption from the definition of infringement allows the generic pharmaceutical manufacturer to make or import and use the patented drug before the expiration of the patent, thus enabling the generic pharmaceutical manufacturer to initiate the FDA regulatory review process before the expiration of the patent. The ability to begin these activities before patent expiration is essential to obtaining FDA approval for

commercialization as of the expiration date of the patent covering the drug. Without this provision, the patent owner would effectively receive the benefit of exclusivity not only during the patent term, but also during the regulatory review of the ANDA.

The purpose of the Hatch–Waxman Act is not, however, to insulate the generic pharmaceutical manufacturer from infringement liability to such an extent that the generic pharmaceutical manufacturer is permitted to start commercialization or even to obtain FDA approval before the expiration of the patent. As a corollary to the privileges granted to the generic pharmaceutical manufacturer, the Hatch–Waxman provision also specifies that the filing of an ANDA for the purpose of obtaining FDA approval for commercialization of a generic drug before the expiration of the patent covering the drug constitutes an act of infringement for which the generic pharmaceutical manufacturer may be liable (45).

The ANDAs that can be the subject of an infringement action under this provision include a paragraph (iv) patent certification, that is, a certification asserting either that the commercialization of the generic drug for which approval is being sought will not infringe the patent covering the innovator's drug or that the patent covering the drug is invalid. As noted above, an ANDA applicant including a paragraph (iv) certification is required by law to notify the patent owner that such an application has been filed. Thus, the patent owner is ensured of receiving notice of his right to commence an infringement action under Section 271(e). If after receiving such a notice the patent owner decides to file a lawsuit for infringement based on the filing of an ANDA including the paragraph (iv) certification, the owner must file the lawsuit within 45 days of receiving the notice of the ANDA filing (46). This action by the patent owner stops the FDA regulatory review of the ANDA, and approval would not be effective until 30 months after the date the patent owner received notification of the ANDA filing (47). The law does give some discretion to the court to shorten or lengthen the 30-month period, depending on the conduct of the parties during litigation (48). The act also provides exceptions to the 30-month period, depending on the outcome of litigation. For example, if the court finds that the patent is infringed and valid (contrary to the ANDA certification) before the expiration of the 30-month period, ANDA approval cannot become effective before the expiration date of the patent (49). This is true even if the 30-month period expires before the patent. If, on the other hand, the court finds that the patent is invalid or not infringed, the ANDA approval may be made effective as of the date of the court decision (50).

These provisions can be summarized as follows. A generic pharmaceutical manufacturer seeking to obtain

FDA approval for a generic drug before the expiration of the patent covering the drug must file an ANDA including a paragraph (iv) certification asserting that the patent will not be infringed by the commercialization of the generic drug or that the patent is unenforceable or that the patent is invalid. The ANDA applicant making this certification must also notify the patent owner of the filing of the ANDA including this certification and provide the details regarding the rationale for the applicant's belief that the patent will not be infringed or is invalid. If the patent owner does not challenge the veracity of the ANDA certification, the ANDA may be approved effective immediately, and with this approval, the ANDA applicant may proceed with the commercialization of the generic drug. If, however, the patent owner does file an infringement action against the ANDA applicant within 45 days after receiving the notification of the ANDA filing, the ANDA may not be approved until 30 months from the date on which the patent owner received notification of the ANDA or the patent expires or the court determines that the patent is invalid or not infringed.

Remedies for the innovator for infringement based on an ANDA filing

If the court finds that an ANDA applicant has infringed a patent by filing the ANDA with a paragraph (iv) certification, the question remains as to what remedy is available to the patent owner. The law explicitly states that the patent owner may not obtain an injunction that would prevent the generic pharmaceutical manufacturer from making, using, selling, offering for sale, or importing the patented drug if the purpose of doing so is solely for the preparation and filing of an application for FDA approval (51). This provision prevents the patent owner from circumventing the provisions of the Hatch–Waxman Act that explicitly exclude these activities from the definition of infringement. However, an injunction can prevent the generic pharmaceutical manufacturer from commercializing the generic drug.

Monetary damages against the infringing ANDA applicant are also an available remedy. However, because the ANDA was not approved, commercial use or sales on which monetary damages could be based are highly unlikely. For the same reason, treble damages and attorney's fees based on willful infringement are, in reality, also unavailable. Perhaps the most important practical remedy for the patent owner is the fact that FDA approval of the ANDA is blocked by an infringement action. Without FDA approval, the generic drug cannot be commercialized, thus preserving the patent owner's exclusivity.

Case study: Bayer AG versus Elan Pharmaceutical Research Corporation

The Hatch–Waxman provisions are demonstrated by the case of *Bayer AG v. Elan Pharmaceutical Research Corporation* (52). Bayer AG and Bayer Corporation (“Bayer”) filed an application and was granted U.S. Patent No. 5,264,446 (the ‘446 patent) in November 1993 covering nifedipine, a drug used for the treatment of hypertension. The ‘446 patent covered nifedipine itself as a composition-of-matter claim, a method for making the drug, as well as a method of treatment using the drug. The purpose of the patent was to provide patent coverage for a sustained-release version of the drug. The patent contained 12 independent claims, and each claim specified a specific surface area (SSA) for the nifedipine crystals used in making tablets of the drug. Specifically, the ‘446 patent covered nifedipine crystals with an SSA of 1.0 to 4 m²/gram in admixture with a solid diluent to result in a sustained-release formulation of the compound.

In April 1997, Elan submitted an ANDA to the FDA seeking approval for a product they claimed was bioequivalent to Bayer’s product containing nifedipine as the active ingredient. Elan’s ANDA covered a once-daily formulation containing 30 mg of active ingredient with an SSA of no less than 5 m²/gram. Pursuant to federal regulations (53), Elan sent notice of its ANDA filing and paragraph IV certification, noting that the nifedipine it intended to manufacture and market did not infringe the claims of Bayer’s ‘446 patent. Bayer filed suit against Elan, claiming both literal infringement and infringement under the doctrine of equivalents. The District Court ruled in favor of Elan on both infringement issues, holding that Elan’s proposed sale of a nifedipine product having an SSA greater than that claimed in the ‘446 patent did not constitute literal infringement and that prosecution history estoppel prevented Bayer from contending infringement under the doctrine of equivalents (54). Bayer appealed the decision of the District Court.

The United States Court of Appeals for the Federal Circuit subsequently upheld the decision of the District Court with respect to both issues of literal infringement and infringement under the doctrine of equivalents. With regard to the issue of literal infringement, the Court of Appeals reasoned that for a product to literally infringe a patent claim, the product in question must contain each limitation of the asserted claim. In other words, the accused product must contain each element of the patented composition to constitute direct infringement of the patent. If any claimed limitation is missing in the accused product, there is no literal infringement as a matter of law. Elan presented evidence at trial that the nifedipine crystals it

intended to use in its product had an SSA equal to or greater than 5 m²/gram. The Court of Appeals held that since the ‘446 patent covered only nifedipine crystals with an SSA between 1.0 and 4.0 m²/gram, the manufacture and sale of Elan’s nifedipine product did not constitute literal infringement.

Bayer alternatively argued that the manufacture and sale of Elan’s nifedipine product constituted infringement under the doctrine of equivalents. As addressed previously, infringement under the doctrine of equivalents can occur if there is not a substantial difference between the limitations contained in the patent and the accused product. However, one caveat of the doctrine of equivalents is the theory of prosecution history estoppel under which a patentee is prevented from claiming infringement for subject matter that was clearly and unmistakably surrendered during prosecution of the patent application. In this case, there was clear evidence that the original application which eventually issued as the ‘446 patent contained claims for nifedipine with an SSA range of 0.5 to 6 m²/gram. During prosecution of the application, the patent examiner rejected Bayer’s claims as obvious over the prior art. In response to the examiner’s rejection, Bayer amended its claims to restrict the scope to only nifedipine crystals with an SSA of 1.0 to 4 m²/gram, claiming that crystals in this range provided unexpected and advantageous bioavailability and sustained-release properties. Elan argued that because Bayer had unequivocally surrendered any claims to nifedipine crystals having an SSA of greater than 4 m²/gram, Elan’s ANDA specifying crystals with an SSA of no less than 5 m²/gram did not constitute infringement under the doctrine of equivalents. The Court of Appeals agreed with Elan’s argument, reasoning that a competitor examining the entire prosecution history of the ‘446 patent would conclude that Bayer had surrendered any claim to a nifedipine drug product having an SSA greater than 4 m²/gram. As a result, the Court of Appeals held that Elan’s ANDA for generic nifedipine did not infringe the claims of Bayer’s ‘446 patent either literally or under the doctrine of equivalents. Consequently, the lawsuit instituted by Bayer was lost, and Elan’s ANDA proceeded to approval by the FDA.

Process Patents and the Hatch–Waxman Act

Process patents (i.e., patents claiming processes for making a drug compound or formulation) are not listed by the FDA in connection with approved drug formulations. Thus, process patents are not subject to the patent certification requirements of ANDAs and do not invoke the Hatch–Waxman procedures relating to

infringement outlined above. If the patent owner learns of the generic pharmaceutical manufacturer's use, sale, offer for sale, or importation of the drug or formulation prepared by the patented process, the patent owner has an action for infringement under the Patent Process Amendment Act, even if the process of making the drug or formulation is conducted outside the United States (55). The same is true if the generic pharmaceutical manufacturer uses, sells, offers for sale, or imports an intermediate useful for making the drug that is prepared by a process claimed in a U.S. patent. Thus, even though process patents do not invoke the important Hatch–Waxman provisions pertaining to infringement, the protection they provide may be invaluable particularly if the only commercially viable means of obtaining the drug is through the patented process. If this is the case, the patent owner may block the commercialization of the generic drug, not by blocking the FDA approval process, but by blocking the generic pharmaceutical manufacturer's ability to obtain the drug compound. Consequently, the protection afforded by the Patent Process Amendment Act, if used correctly, can be an important complement to the protection afforded by the Hatch–Waxman Act. As noted above, there are two important caveats to the Process Patent Amendment Act. A product imported into the United States will not be deemed to infringe on a valid process patent if: 1) the product is materially changed by subsequent processes, or 2) it becomes a trivial and nonessential component of another product. Of course, the terms “material change” and “trivial and nonessential” are vague and open to broad interpretation. The federal courts are still struggling with the meaning of this broad language and with what constitutes infringement.

MOTIVATIONS FOR CHALLENGING A PATENT

Irrespective of the potential liability for patent infringement, the motivation still remains for a generic pharmaceutical manufacturer to challenge the patent(s) covering a drug in an attempt to obtain FDA approval to market a generic version of the drug before the expiration of the innovator's patent(s). There are several incentives for challenging an innovator's patent. For example, although an issued patent is presumed to be valid, occasionally new evidence comes to light after grant that may invalidate one or more of the patent claims. If the generic pharmaceutical manufacturer obtains this evidence and discloses this to the patent owner in the notification required when filing an ANDA with a paragraph (iv) certification, the patent owner may prefer to negotiate a settlement with the generic

pharmaceutical manufacturer rather than risk the possibility of one or more of the claims being declared invalid by the court. Obviously, if the generic pharmaceutical manufacturer hopes to persuade the patent owner to accept such a compromise, the validity of the patent should be fully investigated before filing the ANDA.

If instead of reaching a settlement with the patent owner, the generic pharmaceutical manufacturer successfully challenges the patent, this company has the privilege of keeping the first generic drug on the market and has a head-start on would-be competitors. As a further incentive, the FDA regulations provide an exclusivity period for the first generic drug to enter the marketplace (56). The generic pharmaceutical manufacturer that successfully challenges the patent has an exclusivity period that extends for 180 days after either the first commercial marketing of the generic drug or the date of the first court decision holding the patent invalid or not infringed (57). During this period, no other ANDAs for the same drug may be approved. This period of exclusivity for the generic pharmaceutical manufacturer, coupled with the status of being the first generic drug on the market, can lead to the establishment of a strong market position and a return on the manufacturer's investment in challenging the patent.

CONCLUSION

Growth in the pharmaceutical industry has contributed significantly to the importance of pharmaceutical patents and the Hatch–Waxman Amendments in the United States. The importance of these issues will likely continue to increase as more and more foreign pharmaceutical companies reach toward the lucrative U.S. market for the sale of pharmaceutical products and formulations developed abroad. In the past, most small or midsize foreign pharmaceutical companies have avoided the U.S. markets because of stringent FDA regulations. As the demand for lower-cost pharmaceutical products increases, the profitable U.S. market can no longer be ignored. The balance between the rights of the patent owners and the desire for lower-cost generic alternatives to approved drugs will continue to elevate the importance of the Hatch–Waxman Amendments and will no doubt lead to significant debate as efforts begin for the revision of these provisions.

PEPTIDES AND PROTEINS—BUCCAL ABSORPTION

Ashim K. Mitra

University of Missouri—Kansas City, Kansas City, Missouri, U.S.A.

INTRODUCTION

Background and Rationale

In recent years, proteins and peptides are emerging as a major class of therapeutic agents. Pharmaceutical scientists are faced with the challenges of a) selection of a suitable route of drug delivery and b) formulation of these bioengineered drugs. The most common route of protein and peptide drug delivery has been parenteral. However, this route is associated with pain on administration, resulting in poor patient compliance, and the formulation needs to be sterile. Drugs administered by the gastrointestinal route are subjected to acid hydrolysis and extensive gut and/or hepatic first-pass metabolism. Thus, these protein drugs may exhibit poor oral bioavailability. Noninvasive mucosal and transdermal routes offer effective alternative routes for systemic drug delivery. The transdermal delivery route is limited to potent, lipophilic compounds, does not provide rapid blood levels, and is less permeable than oral mucosa (1). Various absorptive mucosae have been identified and investigated for systemic drug delivery. These include nasal, ocular, pulmonary, rectal, vaginal, buccal, and sublingual. Certain associated drawbacks limit extensive use of the nasal, ocular, pulmonary, rectal, and vaginal mucosae. The buccal and sublingual routes do not have many of these limitations; hence, both routes seem attractive alternative routes for systemic drug delivery. In this article, only buccal drug delivery is addressed.

Advantages

Because of rich buccal vascularity, drugs delivered by the buccal route gain direct access to the systemic circulation and are not subject to first-pass metabolism. Also, therapeutic agents do not come in contact with the acidic digestive fluids secreted by the gastrointestinal tract.

Relative to the nasal and rectal routes, the buccal mucosa has low enzymatic activity, and drug inactivation owing to biochemical degradation is not as rapid and extensive (2).

Excellent accessibility to the buccal mucosa makes application of the dosage form painless, precisely located, and easily removable without discomfort at the end of the application period. The oral cavity consists of a pair of buccal mucosae. Thus, a drug-delivery system can be applied at various sites either on the same mucosa or, alternatively, on the left or right buccal mucosa on different applications. This is particularly advantageous if the delivery system contains a drug or excipient that mildly and reversibly damages or irritates the mucosa.

A buccal drug-delivery system is applied to a specific area on the buccal membrane. Moreover, the delivery system can be designed to be unidirectional in drug release so that it can be protected from the local environment of the oral cavity. It also permits the inclusion of a permeation enhancer/protease inhibitor or pH modifier in the formulation to modulate the membrane or the tablet-mucosal environment at or near that particular application site. Although the irritation is limited to a well-defined area, the systemic toxicity of these enhancers/inhibitors and modifiers can be reduced. The buccal mucosa is well-suited for this type of modification because it is less prone to irreversible damage (3). In the event of drug toxicity, the delivery of drugs can be terminated promptly by removal of the dosage form.

In addition, the buccal route may be useful for unconscious patients and in patients who have recently undergone surgery or have experienced upper gastrointestinal tract disease that would affect oral drug absorption.

Disadvantages

The surface area available for absorption in the buccal mucosa is much smaller than the gastrointestinal, nasal, rectal, and vaginal mucosae. The buccal mucosa is continuously bathed by saliva, and the secreted saliva lowers the drug concentration at the absorbing membrane. These two factors, along with the permeability coefficient of the drug, affect the overall absorption rate by this route. In addition, the buccal mucosa is less permeable than any of the mucosae noted above.

Involuntary swallowing of saliva containing dissolved drug or swallowing the delivery system itself would lead to a major loss of drug from the site of absorption. Talking, eating, and drinking affect the retention of the delivery system and therefore may constitute limitations associated with this route of drug administration (1). In addition, there is a risk of choking on the dislodged drug-delivery device.

Taste, irritancy, and allergenicity also may limit the number of drugs that can be delivered by the buccal route.

ANATOMY AND PHYSIOLOGY OF THE ORAL MUCOSA

Structure

The oral mucosa is anatomically divided into three tissue layers (Fig. 1) (4). These three layers are the 1) epithelium, 2) basement membrane, and 3) connective tissues.

Epithelium

The epithelium consists of approximately 40–50 layers of stratified squamous epithelial cells. The epithelial cells originate from a layer of basal cells, which are cuboidal in shape, undergo continuous mitosis, and move to the surface. As the cells migrate to the surface through the intermediate layers, they differentiate and become larger, flattened, and surrounded by an external lipid matrix (membrane-coating granules). This external lipid matrix

determines the drug permeability of the tissue. Although gingiva (gum) and the hard palate are keratinized, areas such as buccal, sublingual, and the soft palate are nonkeratinized. The thickness of buccal epithelium varies with location and typically ranges from 500 to 800 μm in humans, dogs, and rabbits. The estimated cell turnover time is 5–6 days (5). In addition, the buccal epithelium is also characterized by the presence of intercellular gap junctions.

Basement membrane

The basement membrane (BM) is a continuous layer of extracellular materials and forms a boundary between the basal layer of epithelium and the connective tissues of the lamina propria and the submucosa. The BM can be subdivided into the a) lamina lucida, b) lamina densa, and c) a sublayer of fibrous material. The functions of the BM include providing 1) adherence between epithelium and underlying connective tissues, 2) mechanical support for epithelium, and 3) a barrier to the passage of cells and some large molecules.

Connective tissues

Connective tissues consist of lamina propria and submucosa, if present. The lamina propria is a continuous sheet of connective tissue composed of blood capillaries and nerve fibers serving the oral mucosa.

Vascular drainage from the oral mucosa is principally by way of the lingual, facial, and retromandibular veins. These veins open into the internal jugular vein and thus avoid first-pass metabolism.

The buccal mucosae from monkeys, apes, dogs, pigs, and rabbits possess physiology very similar to that of human buccal mucosa (5).

Fig. 1 Schematic diagram showing the principal components of oral mucosa. (From Ref. 4.)

Permeability

Permeability barriers

The permeability of buccal mucosa lies somewhat between the skin epidermis and intestinal mucosa.

Epithelium: The predominant barrier to drug diffusion resides approximately within the outermost one-third of the epithelium. This is true of both keratinized and nonkeratinized epithelia. Therefore, keratinization is unlikely to offer major resistance to buccal permeation.

Membrane coating granules (MCG): MCGs are spherical or oval organelles (100–300 nm in diameter) found both in keratinized as well as in nonkeratinized epithelia but are different with regard to composition in both epithelia. MCGs discharge their contents into the intercellular space and thus form the permeability barrier.

Permeant factors: The permeation of a drug molecule across the buccal mucosa is dependent on the following.

1. Molecular size—for hydrophilic substances, as molecular weight and molecular size/radius ascends, permeability typically diminishes. Small molecular weight permeants (MW < 100 Da) are rapidly transported through buccal mucosa.
2. Lipid solubility—for non-ionizable compounds, as the lipophilicity rises, the drug permeability typically increases. To maximize the absorption rate, a drug should be available in the salivary film at its solubility limit.
3. Ionization—for ionizable drugs, maximal permeation occurs at the pH at which ionization is least, i.e., where the drug is predominantly in the unionized form (6, 7).

The rate of drug absorption for the transcellular route is pH-dependent. Such dependency results from the fact that the membrane/aqueous partition coefficient for an ionizable drug is pH-dependent.

Basement membrane (BM): The BM has an enormous surface area compared with the epithelium owing to connective tissue papillae, which may affect the effective diffusional pathlength.

Mechanism of Drug Transport

The major pathway of drug transport across buccal mucosa seems to follow simple Fickian diffusion (8, 9). Passive diffusion occurs in accordance with the pH-partition theory. Considerable evidence also exists in the literature regarding the presence of carrier-mediated transport in the buccal mucosa (10, 11). Examination of the equation for drug flux is shown by Eq. 1:

$$J = \frac{DK_p}{h} \Delta C_e \quad (1)$$

where J = drug flux, D = diffusivity, K_p = partition coefficient, ΔC_e = concentration gradient, and h = diffusional pathlength shows that the flux may be increased by decreasing the diffusional resistance of the membrane by making it more fluid, increasing the solubility of the drug in the saliva immediately adjacent to the epithelium, or enhancing lipophilicity through prodrug modification. Because of the barrier properties of the tight buccal mucosa, the rate-limiting step is the movement of drug molecules across the epithelium.

Two pathways of permeation across buccal mucosa are transcellular, in which the passage of drug occurs through the individual cells of the mucosa, and

paracellular, in which the passage of drug occurs through intercellular junctions of the mucosa. Permeability coefficients typically range from 1×10^{-5} to 2×10^{-9} cm/s for oral mucosa (12). The pathway of drug transport across oral mucosa may be studied using: 1) microscopic techniques using fluorescent dyes (12), 2) autoradiography (5), and 3) confocal laser scanning microscopic procedures (13).

FACTORS AFFECTING SYSTEMIC ORAL MUCOSAL DELIVERY

Membrane Factors

Regional differences in both permeability and thickness affect both the rate and extent of drug reaching the systemic circulation (14). Keratinization and composition, although not major factors, of the various oral mucosae affect systemic mucosal drug delivery. Additional factors such as absorptive membrane thickness, blood supply, blood/lymph drainage, cell renewal rate, and enzyme content will also govern the rate and extent of drug absorption into the systemic circulation.

Environmental Factors

Saliva

A major portion of saliva is composed of water (99%) and has a pH of 6.5–7.5 depending on the flow rate and location (15). An increase in the salivary flow rate leads to the secretion of watery saliva. Stimulated salivary secretion affects the film thickness and aids in easy migration of test compounds from one region of the mouth to another. Salivary pH is also important because passive diffusion of unionized drug is the major mechanism of oral absorption (16, 17).

Salivary glands

Drug-delivery systems, therefore, should not be placed either over a duct or adjacent to a salivary duct because this may dislodge the retentive system or may result in excessive washout of the drug or rapid dissolution/erosion of the delivery system, making it difficult to achieve high local drug concentrations. Also, if a retentive system is placed over salivary ducts, the reduced salivary flow rate may produce less/no mucus that is required for proper attachment of a mucoadhesive delivery device.

Movement of the oral tissues

Talking, eating, and swallowing may cause some mouth movement leading to dislodgment of the delivery device (1). The movement of the tongue may also influence the delivery of drugs from a mucoadhesive, retentive system owing to the tongue swiping across the dosage form and adjacent tissues as well as to induction of suction pressures from the tongue compressing against the hard palate.

Dosage Form Design Considerations

Overview

A mucoadhesive buccal drug delivery system should

1. be convenient to apply and unobtrusive when in place,
2. not incorporate a bitter-tasting drug,
3. have a smooth surface rather than a textured surface,
4. preferably achieve unidirectional release of the drug, and
5. use excipients (both diluents and the mucoadhesive polymers) that do not irritate or damage the mucosa, that are nontoxic, and that do not stimulate salivary secretion.

The *size* of the delivery system varies with the type of formulation, i.e., a buccal tablet may be approximately 5–8 mm in diameter, whereas a flexible buccal patch may be as large as 10–15 cm² in area. Mucoadhesive buccal patches with a surface area of 1–3 cm² are most acceptable (18). It has been estimated that the total amount of drug that can be delivered across the buccal mucosa from a 2-cm² system in 1 day is approximately 10–20 mg (12). The *shape* of the delivery system may also vary, although for buccal drug administration, an ellipsoid shape appears to be most acceptable (18). The *thickness* of the delivery device is usually restricted to only a few millimeters. The *location* of the delivery device also needs to be considered. A mucoadhesive retentive system is preferred over a conventional dosage form. A bioadhesive buccal patch would appear to be the most appropriate delivery system because of its flexibility and the area of the buccal mucosa available for its application. The maximal duration of buccal drug retention and absorption is approximately 4–6 h because food and/or liquid intake may require removal of the delivery device.

BIOADHESION

The word *bioadhesion* can be defined as the ability of a material (synthetic or natural) to “stick” (adhere) to

a biological tissue for extended periods (18). The phenomenon of bioadhesion can be visualized as a two-step process. The first step involves the initial contact between polymer and the biological tissue. The second step is the formation of secondary bonds owing to noncovalent interactions.

Biomembrane Characteristics

Oral mucosae are covered with mucus that serves as a link between the adhesive and the membrane. Mucin is a polyelectrolyte under neutral or slightly acidic conditions because of the terminal sialic acid residues having a pK_a value of 2.6 (19). At physiological pH (7.4), the mucin molecule is polyanionic, which contributes to bioadhesion.

Adhesive Characteristics

A variety of polymers including water-soluble and water-insoluble and ionic and non-ionic hydrocolloids and water-insoluble hydrogels can be used in bioadhesive systems (20). Factors affecting the bioadhesive properties of the polymer include the following.

Molecular weight and polymer conformation

In general, the adhesive strength of a polymer increases with molecular weights greater than 100,000 (21). The molecule must have adequate length to allow chain interpenetration into the mucus layer. However, the size and conformation of the polymer molecule play an important role as well (22).

Cross-linking density of the polymer

The strength of mucoadhesion decreases with an increase in cross-linking as this leads to a decrease in the polymer's diffusion coefficient (23) and chain segment flexibility and mobility (which in turn reduces interpenetration).

Charge and ionization of the polymer

Anionic polymers provide better efficiency than do cationic or uncharged polymers with respect to both adhesiveness and toxicity (24). Also, polymeric adhesives with carboxyl groups are preferred over those with sulfate groups (25).

Concentration of the polymeric adhesive

In general, the more concentrated the polymeric adhesive becomes, the more the bioadhesive strength diminishes.

The coiled molecules become solvent-poor in a concentrated solution, which, in turn, decreases the available chain length for interpenetration into the mucus layer. Therefore, a critical concentration of the polymeric adhesive is required for optimum bioadhesion (26).

pH of the medium

pH influences the charge on the surface of the mucus and the polymer (27). Charge density on the surface of mucus will vary with pH owing to the differences in dissociation of the functional groups on the carbohydrate and amino acid moieties.

Hydration of the polymer

Swelling affects bioadhesion (28), although an increase in the degree of swelling does not always result in an increase in the bioadhesive strength. However, a high water activity is required to hydrate the mucoadhesive component to expose the bioadhesive site(s) for secondary bond formation, to expand the gel to create pores of sufficient size, and to mobilize all flexible polymer chains for interpenetration. A critical degree of hydration of the mucoadhesive polymer is needed for optimum bioadhesion (20). A greater degree of hydration lowers the adhesive strength owing to the formation of a slippery mucilage.

Theories of Bioadhesion

In general, both physical and weak chemical bonds are responsible for mucoadhesion. Physical/mechanical bond formation can be explained as the entanglement of the adhesive polymer and the extended mucin chains. When this diffusion is mutual, it leads to maximum bioadhesive strength.

Attaching bonds may be either primary owing to covalent bonding or secondary owing to electrostatic, hydrogen, or hydrophobic bonding. Electrostatic or hydrogen bonding results primarily because of hydroxyl ($-\text{OH}$), carboxyl ($-\text{COOH}$), sulfonate ($-\text{SO}_3\text{H}$), and amino ($-\text{NH}_2$) groups. Several theories of bioadhesion have been proposed, i.e., wetting, diffusion, electronic, fracture, and adsorption. The mechanism of bioadhesion appears to be best explained by a combination of the wetting, diffusion, and electronic theories.

Measurement of Bioadhesion

Measurement of bioadhesion not only helps in screening the candidate polymer but also assists in studying the mechanism of bioadhesion. However, performance of

the final dosage form containing the polymer and the drug is the best test for bioadhesion.

In vitro measurements

Measurement of either tensile or shear stress is the most commonly used in vitro method to measure bioadhesion. All in vitro measurements provide a rank order of bioadhesive strength for a series of candidate polymers. Measurement of tensile strength involves quantitating the force required to break the adhesive bond between the test polymer and a model membrane. This method typically uses a modified balance or tensile tester. A section of freshly excised rabbit stomach tissue with the mucosal side exposed is secured on a weighed glass vial and placed in a beaker containing USP-simulated gastric fluid. Another section of the same tissue is secured onto a rubber stopper with a vial cap with the mucus side exposed (Fig. 2). A small quantity of the test polymer is placed between the two mucosal tissues. The force required to detach the polymer from the tissue is then recorded (29). Measurement of shear strength involves quantitating the force that causes the polymer to slide in a direction parallel to the plane of contact between the polymer and the mucus. This method uses a glass plate suspended from a microbalance on which the test polymer is coated (Fig. 3). This plate is then dipped in a temperature-controlled mucus sample. The force required to pull the plate out of the mucus sample is determined under constant experimental conditions (22).

Additional in vitro methods include adhesion weight (30), fluorescent probe (24), flow channel (31), mechanical spectroscopic (32), falling film (33), colloidal gold staining

(From Ref. 22.)

(34), viscometric method (35), thumb test (36), adhesion number (36), and electrical conductance (36).

In vivo measurements

In vivo methods are relatively few and measure the residence time of bioadhesives at the application site (36). Techniques such as γ -scintigraphy, perfused intestinal loop and radiolabeled transit studies using ^{55}Cr -labeled bioadhesive polymer (37), and $^{99\text{m}}\text{Tc}$ -labeled polycarbo-phil (38) have been used for this purpose.

Bioadhesive Polymers in Buccal Drug Delivery

A variety of water-soluble and water-insoluble polymers of both synthetic and natural origin (20) have been studied as bioadhesives.

Overview

Bioadhesive polymers are used mainly to overcome the short residence time of drug and the dosage form to improve localization of the drug and to achieve controlled or sustained release of the drug. Bioadhesive polymers can be divided into three broad categories: 1) "wet" adhesives,

i.e., polymers that become sticky on hydration, 2) polymers that are electrostatic in nature and adhere primarily owing to nonspecific and noncovalent interactions, and 3) polymers that can bind to a specific site on the cell surface (39).

An ideal bioadhesive should

- be nontoxic, nonabsorbable, and nonirritating to the mucus membrane,
- form a strong noncovalent bond with the mucin-epithelial cell surfaces,
- allow easy incorporation of drug and should not offer hindrance to drug release, and
- not decompose on storage or during the shelf life of the dosage form.

Some of the other desirable characteristics of the polymer have been presented previously in *Bioadhesion*.

Drug release from soluble polymers is accompanied by the gradual erosion-type dissolution of the polymer. Therefore, polymer dissolution/drug diffusion may be the overall hybrid mechanism of release. Drug release from nonsoluble hydrogels generally follows Fickian or non-Fickian diffusion kinetics (40). The mechanism of release may be determined by modeling the drug release (first 60%) to the empirical equation (Eq. 2),

$$\frac{M_t}{M_\infty} = kt^n \quad (2)$$

where M_t/M_∞ = fraction of drug released, k = kinetic constant, t = time, and n = diffusional exponent. The mechanism of drug release may be Fickian diffusion when the value of $n = 0.5$; anomalous (non-Fickian) transport when $n = 0.5 < n < 1.0$, and case-II transport when $n = 1.0$. A value of n greater than 1 signifies super case-II transport as the mechanism of drug release (41).

DOSAGE FORMS

Several bio/mucoadhesive dosage forms have been developed, and mechanism(s) of bioadhesion have been delineated.

Buccal Dosage Forms

Buccal mucosa presents a relatively smooth and immobile surface for the placement of a bioadhesive dosage form. The amount of drug that can be incorporated is limited because of the size limitation of the buccal dosage form. In general, a drug with a daily requirement of 25 mg or less is suitable for buccal delivery. Drugs with a short half-life, requiring sustained/controlled delivery, or exhibiting poor

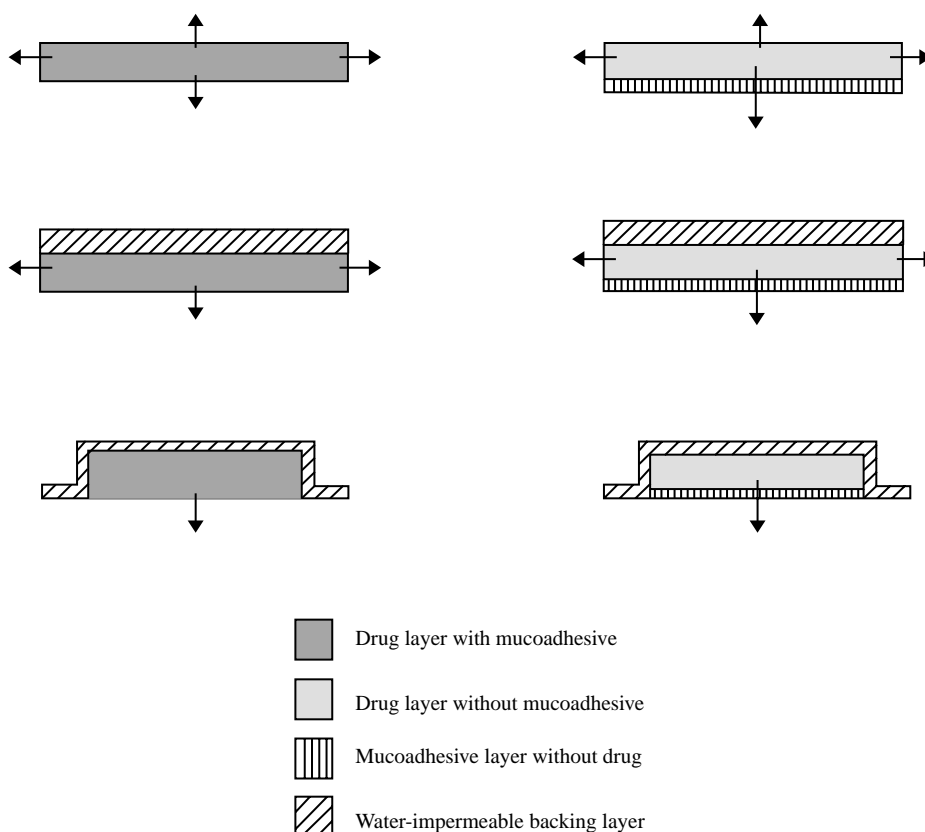

Fig. 4 Schematic diagram showing the geometric designs of buccal delivery devices. (From Ref. 91.)

aqueous solubility and drugs that are sensitive to enzymatic degradation may be delivered successfully across the buccal mucosa. The dosage forms developed for this purpose include tablets, adhesive patches, adhesive gels, and adhesive ointment. Adhesive tablets and patches can be formulated to release the drug either unidirectionally or multidirectionally by varying the extent and permeability of the backing (Fig. 4).

Formulation Development of Buccal Dosage Forms

Novel dosage forms such as adhesive tablets, patches, gels, and ointments have been developed primarily for systemic delivery of therapeutic agents. These dosage forms are also capable of providing sustained drug delivery.

Buccal dosage forms can be of 1) reservoir type and 2) matrix type.

Reservoir type

Drug formulations of the reservoir type are surrounded by a polymeric membrane, which controls the release

rate. Reservoir systems present a constant release profile, provided 1) the polymeric membrane is rate limiting and 2) an excess amount of drug is present in the reservoir.

Matrix type

Drug is uniformly dispersed in the polymer in matrix-type systems, and drug release is controlled by the matrix. Drug molecules dispersed in the polymer have to dissolve in the medium and then diffuse through the polymer network. Therefore, a drug dispersion and drug-depletion zone always exists in the matrix. A thin hydrodynamic diffusion layer also exists at the interface of the drug and the matrix. A matrix system may result in a constant release profile only at early times when the drug-depletion zone is rather insignificant.

The parameters that determine the release rate of a drug from a delivery device include polymer solubility, polymer diffusivity, and thickness of the polymer diffusional path, and the drug's aqueous solubility, partition coefficient, and aqueous diffusivity. Finally, the thickness of the hydrodynamic diffusion layer, the amount

of drug loaded into the matrix, and the surface area of the device all affect the drug's release rate.

Buccal adhesive tablets

Adhesive tablets may be either monolithic or multilayered devices. Monolithic tablets can be prepared by conventional techniques of either direct compression or wet granulation. These tablets provide the possibility of holding large amounts of drug. Using either compression or spray coating, a partial coating of every face except one that is in contact with the mucosa with a water-impermeable material such as cellophane, hydrogenated castor oil, Teflon, ethyl cellulose, etc., may cause unidirectional drug release. Multilayered tablets may be prepared by adding each formulation ingredient layer by layer into a die and by compressing it on a tablet press (Fig. 4). These tablets can be designed to deliver drugs either systemically or locally. For multilayered tablets, incorporation of the drug into the adhesive layer, which is immediately adjacent to the mucosal surface, may aid in optimizing bioadhesion.

Buccal adhesive patches

Adhesive patches may also be monolithic or multilayered devices of the reservoir or matrix type for either systemic or local drug delivery. Two primary types of manufacturing processes are usually used to prepare adhesive patches. These include solvent casting and direct milling (with or without a solvent). The intermediate product is a sheet from which patches are punched. A backing is then applied to control the direction of drug release and to minimize deformation and disintegration of the device during residence in the mouth. Preparation of adhesive patches by the solvent-casting method involves casting of appropriately prepared aqueous solutions of either polymer (for drug-free patches) or a drug/polymer mixture onto a backing layer sheet mounted on a stainless steel plate by means of a frame. Drying may then be performed by perfusing with a thermostated stream of water or by air drying. The temperature is typically selected based on the excipients used in the formulation. On complete drying, the laminate may be cut into the desired shape and size

Fig. 5 Schematic diagram showing the design of mucoadhesive buccal patch. (From Ref. 81.)

using a suitable punch and a die set. Preparation of adhesive patches by direct milling is done by homogeneously mixing the drug and the bioadhesive, with or without the aid of a solvent, using a two-roll mill. The polymer/drug mixture may then be compressed to its desired thickness, and patches of appropriate size may be cut or punched out. The polymer/drug mixture prepared with a solvent may require an additional drying step afforded by air or oven drying (Fig. 5).

Design of Experiments

A formulation may be evaluated for both in vitro and in vivo release and mucosal permeation by designing appropriate experiments.

In vitro release/permeation studies

In vitro release studies may be designed depending on the shape and application of the dosage form because no standard method is available. A survey of the literature indicates that the apparatus used for the release study varied from a typical USP type I/II apparatus to a rotating basket immersed in a beaker with agitation conditions being rotational (50–250 rpm) to magnetic stirring or mechanical shaking (39). A variety of testing media have been used such as distilled water, chloroform, phosphate buffer, saline, a mixture of methanol, and water, etc. (39). In vitro release studies provide valuable information regarding the behavior of the delivery device and the mechanism of drug release from the delivery device.

In vitro permeation studies can be conducted using a glass diffusion cell with the buccal tissue mounted between the two halves of the cell, which may be filled with constantly stirred buffer solutions. Buccal mucosa may then be excised from the canine or porcine or rabbit cheek immediately after sacrifice. Such permeation studies may provide meaningful results on the simultaneous processes of drug transport and metabolism in the tissue. Attention must be given to the viability of the excised tissue under in vitro conditions. Electrophysiologic characterization appears to be a valuable tool to indicate the viability of the tissue after excision. To retain tissue viability, continuous bubbling with O_2/CO_2 mixtures and the addition of glucose to the buffer media may be useful. Viability can be determined using MTT assay and confocal imaging of vital staining (42). Alternatively, cell culture technique can be used, where by several parameters can be varied to arrive at an optimum delivery device. This technique also helps in understanding the possible mechanism of drug transport and therefore may provide strategies for modification of either the drug molecule or the drug-delivery device (43).

In vivo absorption studies

Animal studies: Only a small number of absorption studies have been conducted in animals. This may be because buccal administration of drugs to animals is difficult and often produces artifactual results (44). Animals selected as models should be representative of human absorption, tissue, enzymes, degree of keratinization, etc. Conscious or anesthetized animals may be used for absorption studies. Conscious animals should be preconditioned by administering placebos for several consecutive days. The experimental dosage form may then be administered/applied to the buccal mucosa. Absorption may be followed by monitoring plasma and/or urinary drug concentrations as well as the amount of drug remaining in the dosage form after the experiment.

Human studies: Human studies are conducted after the dosage form has been optimized with respect to release of the drug, shape of the dosage form, amount of the drug to be incorporated, and completion of preclinical toxicity studies in animals. Human volunteers may be asked to place the dosage form on the buccal mucosa, and the absorption process may be followed by monitoring the amount of drug remaining in the dosage form after certain time intervals and/or by sampling biological matrices (blood, urine, etc.) with appropriate pharmacokinetic/pharmacodynamic analyses. The amount of drug remaining in the dosage form may reflect absorption only if the absorption step is not rate limiting, and an attempt to prevent swallowing a drug/saliva solution has been made (45).

Evaluation of toxicity and irritation

Irritation is very subjective and may differ widely from treatment to control subjects. Most irritation occurs as a result of penetration enhancers. Evaluation of toxicity and irritation should be concerned with: 1) mucosal tissue irritation, 2) extent of damage to the mucosal cells, and 3) rate of recovery.

Mucosal tissue irritation: Irritation is a complex phenomenon involving interaction among the solution properties of the vehicle, mucosal transport, biological transport, and local drug disposition. To date, no definite relationship has been established between the structure of a penetration enhancer, for example, and the degree of irritation it may cause following buccal application. However, a relationship between the pK_a value of an ionizable compound (benzoic acid derivatives) and irritation as measured by the degree of erythema has been reported (46, 47). Azacycloalkanone enhancers demonstrated more irritancy with alkyl than those with alkenyl chains (48). In general, it would appear that the

most effective penetration enhancers induce the greatest degree of irritation to mucosal tissues.

Extent of Damage to Mucosal Cells: Permeation enhancement implies possible alteration of the protective permeability barrier either by: 1) an increase in the fluidity of intercellular lipids (relatively nontoxic) and/or 2) extraction of intercellular lipids or denaturation of cellular proteins (much more damaging/toxic). Therefore, it is imperative that the permeation enhancer: 1) exert a reversible effect, 2) not be systemically absorbed, and 3) not cause cumulative toxicity or permanent changes in the barrier properties. Application of up to 1% sodium lauryl sulfate or cetylpyridinium chloride to the ventral surface of the tongue of dogs resulted in desquamation, widening and separation of keratin (49). The buccal mucosa of rabbits treated with 0.5% sodium deoxycholate or 0.1% sodium lauryl sulfate demonstrated loss of surface epithelial cells (50). Sodium taurocholate and lysophosphatidyl chloride increased buccal insulin absorption in dogs with no mucosal irritation (51).

Methods used to assess membrane damage: Several methods are commonly used to estimate the degree of damage to biological membranes induced by various permeation enhancers. The following methods are a partial listing:

1. morphological examination by scanning or transmission electron microscopy (52),
2. morphological examination using light microscopy and appropriate staining, e.g., hematoxylin and eosin (H&E) (53),
3. determination of the extent of hemolysis caused by a permeation enhancer (54),
4. determination of the release of cellular constituents, e.g., lactate dehydrogenase (LDH) (55),
5. measurements of the changes in the electrical resistance of the membrane,
6. measurements of the changes in the permeability to various markers, e.g., insulin, mannitol, and FITC-dextran, and
7. measurements of changes in cilia movement, e.g., with nasal mucosa.

Rate of recovery of mucosal membranes: The rate of recovery is generally inversely related to the extent of membrane damage, i.e., a greater and more rapid recovery from permeation enhancers that induce minimal damage such as acylcarnitines (56) and sodium glycocholate compared with enhancers such as sodium deoxycholate (57) and polyoxyethylene-9-lauryl ether. The permeability of the tight junction is sensitive to the extracellular calcium concentration. Resealing of tight junctions has been shown to be accelerated if there is a

high extracellular calcium concentration rather than an elevated cytoplasmic calcium concentration (58).

Miscellaneous toxicity concerns: Additional toxicity concerns include interference with normal metabolism and function of mucosal cells, e.g., water absorption by these cells (59). The unconjugated bile acids are known to block amino acid metabolism and glucose transport (60). There is a possibility of biotransformation of these enhancers to toxic or carcinogenic substances by hepatic monooxygenases. Absorption of permeation enhancers into the systemic circulation can also cause toxicity, e.g., azone and hexamethylene lauramide (61), which are absorbed across skin. Moreover, changes in membrane fluidity may alter the activity of membrane-bound transport proteins and enzymes.

BUCCAL DRUG DELIVERY OF PEPTIDES AND PROTEINS

Buccal drug delivery avoids acid- and enzyme-mediated degradation and hepatic first-pass metabolism. However, the bioavailability of therapeutic polypeptides and proteins is generally very low (<5%) owing to low lipid solubility

and their inherent larger molecular weight compared with conventional small molecules. Degradation of proteins and peptides by enzymes such as aminopeptidases, carboxypeptidases, several endopeptidases, and esterases is also a reason for their low bioavailability. The premise of passive transport as the mechanism of peptide and protein absorption across the buccal mucosa is widely accepted. Endocytotic processes are not apparent in buccal epithelium. No active or carrier-mediated peptide transport systems are present in the buccal epithelium except those responsible for the absorption of a few amino acids such as glutamic acid (anionic) and lysine (cationic) (62). In general, the various aspects addressed thus far can be applied for buccal drug delivery of peptides and proteins (Table 1). It can be noted from the data presented in Table 2 that in general as the molecular weight of the peptide increases, the bioavailability decreases. This suggests that the peptides and proteins, being hydrophilic and globular in nature, are transported by paracellular route.

Biological Activity

Biological activity is the most important concern with the delivery of therapeutic peptides and proteins. Suscepti-

bility of these molecules to denaturation by various manufacturing processes may seriously limit the number of methods that can be used in the fabrication of delivery systems. Important process variables such as temperature, pressure, and exposure to organic solvents, etc., during manufacturing need to be considered. The formulation strategies presented above can be applied to the development of peptide and protein formulation in general, or they can be modified according to special needs.

Temperature

High temperatures can break native S—S bonds and form new S—S bonds that can “lock” the protein into a denatured configuration. Low pH, sodium dodecyl sulfate, Tween 80®, chaotropic salts, and exogenous proteins have been used to protect proteins from thermal inactivation (83). Ethylene glycol at 30–50% was used as a protectant of antiviral activity of β -Interferon preparations (84). Human serum albumin was used in recombinant human interferon- $\beta_{\text{ser-17}}$, which resulted in increased thermal stability (47). Water-soluble polysaccharides such as

dextrans and amylose and point-specific (site-directed) mutagenesis (85) have also been used to increase thermal stability of therapeutic proteins and peptides.

Pressure

Proteins are not very sensitive to pressure changes, and only at large values of pressure do they exhibit conformational changes observed when denatured by heat or changes in solution pH (86). A model enzyme (protein), namely, urease, did not lose much of its activity until the compaction pressure exceeded 474 mPa, above which 50% of the relative activity was lost (87).

Pharmacokinetics and Pharmacodynamic Responses

Pharmacokinetics and pharmacodynamic responses have to be evaluated separately. Initial consideration of a drug candidate for buccal delivery may be its low biological half-life ($t_{1/2}$) possibly owing to high first-pass metabolism and gastrointestinal degradation. It should be noted that both the t_{max} and C_{max} increase (88) with an increase in

$t_{1/2}$. The fraction of the therapeutic peptide absorbed via the oral mucosa should not be calculated from pharmacodynamic response data alone because the efficiency of peptide absorption with respect to its pharmacodynamic response depends not only on the total dose absorbed but also on the rate at which the peptide is taken up by the target organ. Pharmacokinetics after buccal dosing can also be performed using moment analysis (89).

Enzymatic Degradation

The proteolytic activity of the buccal mucosa presents a significant barrier to the delivery of proteins and peptides. Buccal homogenate studies may provide initial data concerning the rate and extent of biochemical degradation of peptides when delivered by the buccal route (90). The disadvantage of homogenate studies includes the inability to distinguish among cytosolic, membrane-bound, and intercellular proteolytic activity. Because protein and peptide transport can be either trans- or paracellular in nature, the exact location of these proteolytic enzymes is important.

A novel concept of using bioadhesive polymers such as derivatives of poly(acrylic acid), polycarbophil, and carbomer to protect therapeutically important proteins and peptides from proteolytic activity of enzymes, endopeptidases (trypsin and α -chymotrypsin), exopeptidases (carboxypeptidases A and B), and microsomal and cytosolic leucine aminopeptidase (91) has been developed. However, cysteine protease (pyroglutamyl aminopeptidase) may not be inhibited by polycarbophil and carbomer (91).

Table 3 Exemplary absorption enhancers under investigation for buccal administration

Class	Exemplary compounds
Chelators	EDTA
Surfactants	Benzalkonium chloride Brij 35 Laureth-9 Sodium dodecylsulfate
Bile salts	Sodium deoxycholate Sodium glycocholate
Fatty acids	Sodium myristate
Peptidase inhibitors	Aprotinin
Miscellaneous	Chondroitinase ABC 1-Dodecylazacycloheptan-2-one Cyclodextrin Quillajasaponine Sodium salicylate

Enzyme Inhibitors

Protease inhibitors are generally used as enzyme inhibitors. These include aprotinin (79), bestatin (92), chondroitinase, and hyaluronidase. According to several published reports, these inhibitors appear to lack adequate effectiveness when administered simultaneously with various peptides in vivo (79).

Permeation Enhancers

Generally, these enhancers fall into six categories: 1) chelators (e.g., EDTA, EGTA); 2) surfactants, which are subdivided into non-ionic, e.g., laureth-9, polysorbate 80, sucrose esters and dodecylmaltoside, cationic; (e.g., cetylmethylammonium bromide), and anionic (e.g., sodium dodecyl glycocholate, sodium lauryl sulfate); 3) Bile salts and other steroidal detergents (e.g., sodium glycocholate, sodium taurocholate, saponins, sodium taurodihydrofusidate, and sodium glycodihydrofusidate); 4) fatty acids (e.g., caprylic acid); 5) nonsurfactants (e.g., 1-dodecylazacycloheptan-2-one (Azone), salicylates, and sulfoxides); and 6) enzymes (e.g., phospholipases, hyaluronidases, neuraminidase, and chondroitinase ABC).
